This willingness to go beyond strict scientific consensus is visible elsewhere in WDFW's own recent guidance. In its 2025 Riparian Management Zones Map user guide, the agency states plainly that it recommends protecting the entire stream network — **including non-fish-bearing streams** — because it **found no science justifying weaker protection for those streams**, and it explicitly acknowledges that this recommendation **departs from widespread practice elsewhere of applying narrower buffers to non-fish-bearing streams.** Once again, not exactly site specific nor science-informed.

I raise this not to criticize the recommendation itself, but to highlight that WDFW is properly transparent in stating that its own proposed standard is a policy judgment that goes beyond, and diverges from, common practice — not a settled scientific consensus that other jurisdictions have simply failed to catch up to.

I'd also note that the tree-height method was primarily developed in wet, sloped, forested landscapes in the western part of the state. Applying it uniformly to different ecological settings — drier regions, different soil types, different topography, different vegetation communities — extends a coastal-forest-derived standard well beyond the conditions it was originally studied in, without independent validation on those drier settings affected.

Conservative, protective buffers are reasonable public policy, especially for salmon recovery and water quality. But I'd ask that our local planning materials and public discussions describe and consider SPTH200 accurately: as a policy choice with a specific origin and scope — one that the issuing agency itself acknowledges departs from common practice in places — not as an unambiguous scientific fact. That distinction matters, because it affects how much flexibility should be built into local ordinances for site-specific review, alternative mitigation, or variance requests — flexibility that's harder to justify if the standard is presented as scientifically absolute rather than as a reasonable-but-debatable policy judgment.

I would also ask that such policy discussions include consideration of non-scientific issues such as private property rights, compensation for property designated as a needed buffer zone, and relief from the ongoing imposition of property taxes on property taken for use as such buffer zones.

Thank you for your attention to this matter.

Dave Campbell

Download document (PDF) (/sites/default/files/publications/02671/wdfw02671.pdf)

Overview

Riparian areas occupy the transition zone that begins at the stream's edge and extends upland. These areas provide habitat to an estimated 85% of Washington's terrestrial vertebrate species, and riparian vegetation provides critical ecosystem functions that support and protect instream health. Protection of these areas is especially important for salmon recovery efforts, and other decision-making affecting threatened or endangered species. For these reasons, WDFW identifies riparian habitat as a Priority Habitat and recommends that local governments designate and protect Riparian Management Zones (RMZs) as a Fish and Wildlife Habitat Conservation Area (FWHCA), a type of critical area under the Growth Management Act.

After extensive review of available evidence, WDFW identified a method to define the upland RMZ boundary according to the lateral distance over which essential riparian functions are provided. This Site Potential Tree Height at 200 years ($SPTH_{200yr}$) is the estimated average height attained by dominant trees in that location after 200 years of growth. In addition to serving directly as shelter and sustenance to many species, trees contribute shade, leaf litter, and large woody debris to streams; they also reduce pollutants, attenuate destructive overbank flooding, and enhance many forms of recreation along watercourses. In addition to these functions, intact RMZs also provide direct benefits to surrounding communities by filtering pollutants, stabilizing streambanks, reducing flooding, and supporting overall watershed resilience. Tree height therefore provides a generalized yet flexible means to estimate the distance over which riparian functions are provided.

The $SPTH_{200yr}$ estimate is obtained by identifying the tallest species of tree growing in the area and the soil type. The RMZ's width is a distance of one $SPTH_{200yr}$ measured from the stream's bankfull width, active floodplain, or outer edge of the channel migration zone (CMZ), whichever is wider. In places where tree height is less than 100 feet, the RMZ width is set to a minimum distance of 100 feet to account for the pollutant removal function provided by RMZs. As described in Riparian Ecosystems Volumes 1 and 2, a 100-foot RMZ typically provides 95% pollution removal for phosphorus, sediment, most pesticides, and approximately 85% for surface nitrogen. Because we found no science that justified lesser protections for non-fish-bearing streams, we recommend that RMZ protections be provided to the entire stream network – this is a departure from widespread practice of protecting a narrower RMZ for non-fish-bearing streams.

The PHS RMZ map is intended to provide local jurisdictions with estimated locations of RMZs delineated based on a $SPTH_{200yr}$ standard to support the designation and protection of critical areas. The map was created using best available scientific data estimating stream locations, likely tree species, and the maximum tree height at 200 years for streams across all of Washington. ***The map represents estimated locations only and site-scale delineation of an RMZ critical area requires field verification.***

Subject: Critical Areas Comments

Good Evening,
Thank you for the opportunity to provide my personal commentary on the draft critical areas ordinance code updates. I am a licensed professional civil engineer in Washington state and have spent the last 14 years of my career working in Walla Walla. In reviewing the existing code and draft code updates there are several sections that will be detrimental to development within the City of Walla Walla.

Overall my two main concerns in review of the Draft Code are below.

1. It appears the author's focus when rewriting this chapter was on specific "Critical Areas", and not the entirety of "Critical Areas" as defined in the Code. The focus appears to be around water bodies, drainages, streams, wetlands, or associated buffers. However, the underlying City's Municipal Code defines a Critical Area below.

   "Critical areas"
   include any of the following areas or ecosystems: aquifer recharge areas, fish and wildlife habitat conservation areas, frequently flooded areas, geologically hazardous areas, and wetlands, as defined in Chapter **36.70A** RCW and this chapter.

   This definition, a review of the City's Critical Area Maps, and a review of the Code shows that nearly 100% of the City of Walla Walla falls within a single, or multiple, defined Critical Areas making all property within any Critical Area subject to the existing code and future code amendments.

2. What are the economic impacts associated with property valuations and taxes for properties that are now further encumbered? Has the Walla Walla County Tax Assessor and the City of Walla Walla conducted an evaluation of the potential tax liability associated with this change?

In addition to my two overall concerns about the author's intent and Draft Ordinance – the City's website (Critical Areas Ordinance | City of Walla Walla) has other language/statements that is not readily identified in the Code update.

Website Statement -
Walla Walla is in a dryland ecosystem. Within dryland ecosystems, WDFW's new science calls for cities to set a site-specific Riparian Management Zone (RMZ) area with a 100-foot minimum width of existing riparian vegetation, whichever is greater. This distance is generally needed to remove most pollutants and protect water quality. The state's mapping tool shows where this 100-foot RMZ should be applied. Overall, following this new BAS will significantly increase buffer width requirements for both fish-bearing and non-fish-bearing streams in Walla Walla.

Comments –
1. Where is an RMZ defined in this code? I do not see any references to RMZ being defined or delineated in the Draft Ordinance.
2. What is the maximum width of an RMZ identified within the City of Walla Walla? The maximum width reference is in regards to the statement on the City's website noting - "whichever is greater".

Comment – Can the City please provide definitions to the following based on language in the code.

Define “Reasonable Use”
Define "Reasonable Economic Use"
Define a "Trail Corridor"

Chapter 21.04.085(B)(2-3, 7-23) Critical Areas – Allowed Activities
Comment – The allowed uses generally appear to be associated with maintenance, or non-invasive uses, in and around water bodies. If a use is not outright allowed, is it disallowed? There are a host of uses within the defined Critical Areas inside city limits that are needed such as Commercial, Residential, and Public uses that need to be allowed without the need for professional studies or approval by the Director. This section does not reference other Allowed Uses as defined in 21.04.220.

Chapter 21.04.085(B)11)–

Comments –

1. Is the above Allowed Use for Minor Sitework applicable to All Critical Areas?
2. Minor Site Investigation that displaces more than 5 cubic yards of material shall require submittal of specific plans and restoration plans.
   As a point of emphasis a typical geotechnical test pit (2x6x12) is in excess of 5 CY.

- What is the “Specific Plans and Restoration Plans” required? This creates a substantial burden on our geotechnical engineers and due diligence and obtaining advance approvals.
- Is this 5 CY value cumulative for Minor Site Investigative Work, per project, per discipline/individual action performed?
  - IE – If a single test pit is excavated that is beyond 5 CY, other minor work listed is now responsible for “Specific Plans and Restoration Plans”?

3. How does damage to native trees/plants/shrubs in Critical Areas viewed when it comes to clearing property lines, locating/establishing project boundaries, pins, etc.?

Chapter 21.04.090(B)(2-3)
Comments –

1. Define what is to be included in an Exception Request. The terms used in this section are very subjective, "including mitigation plan, if necessary," and "any other related project documents", "special studies" are too vague to understand, and/or scope for a project.
2. The exception is at the sole discretion of the "Director". What is the appeal process if applicant disagrees with the "Director"? Is the "Director's" decision binding?

...the applicant demonstrates that other permitted uses in the areas that have less impact on the critical area and buffer are not technically feasible as an alternative."

Comment –

1. Who determines if the Applicant demonstrates sufficient information?

...to allow for reasonable economic use of the property; and upon request, the director may require the applicant to provide a neighborhood analysis that evaluates the surrounding conditions in the immediate vicinity to verify that the applicant's request is consistent with the minimum necessary reasonable use criteria.

Comments –

1. What is the scope of a neighborhood analysis and who is the qualified professional that can prepare this document?
2. What are the "Minimum necessary reasonable use criteria"?

Chapter 21.04.085(B)(2-3)9.d. -

“Sensitive area and/or buffer widths shall be increased, where possible, equal to the width of the trail corridor, including disturbed areas; and”

Comment – See above request to define a “Trail Corridor”.

Chapter 21.04.130(A)
Comments -

- Are all future building permits subject to a critical areas report given the presence of one or multiple critical areas encompassing the vast majority of the City of Walla Walla and it’s UGA?

Chapter 21.04.200(B) –
Comments

1. The 10-year time of travel is considered a CARA by the City of Walla Walla. This is classified as a Critical Area.
2. How are allowed uses such as Commercial, Industrial, and Residential Uses defined for this area?
3. How are the impacts to Walla Walla County being addressed based on the City’s Code for this section? The CARA effectively goes to the ridge of the Blue Mountains in encumbers substantial property outside the City of Walla Walla.

Chapter 21.04.320(B)(3) –
Comments –
Note the statement in this chapter “…and other critical areas…”. Are citizens required to do complete critical areas studies for all projects within 250’ of any critical area?

In closing, it would appear that the wording and updates to this code chapter have been hasty and without a full understanding and appreciation of the impacts social, environmental, economic impacts. I would like to see further study to address the above concerns and further clarifications added to the code to avoid unforeseen hardships on the citizens of our community.

Respectfully,

Michael Melder, PE
Civil Engineer

Re: Proposed Critical Areas Ordinance Amendments

Dear Council Members and Commissioners,

I support the City's efforts to protect critical areas and the environmental functions they provide. My concern is with establishing a blanket 100-foot minimum buffer without adequately considering site-specific conditions and the significant impacts this change could have on individual properties.

The City has indicated that the proposed amendments are based on Best Available Science. I believe it is important to distinguish between the scientific recommendations and the City's decision to establish a uniform 100-foot development restriction.

WDFW's methodology recognizes that riparian areas should be evaluated based on site-specific conditions, including vegetation, soils, topography, and habitat functions. Property owners should have an opportunity to demonstrate the appropriate buffer based on the actual conditions present on their property.

Impact on Existing Homes and Property Owners

The City should also consider the impact on existing homes and homeowners, not just future development. A new 100-foot buffer could significantly restrict reasonable improvements such as additions, remodels, garages, accessibility improvements, and other necessary changes.

A homeowner who purchased property under the existing regulations should not unexpectedly lose a substantial portion of the property's reasonable ability to be improved simply because the regulations have changed.

Citywide Housing and Growth Impacts

The City should also evaluate the cumulative impact of a 100-foot buffer across Walla Walla. With numerous waterways and areas potentially affected by critical-area regulations, this requirement could affect a significant amount of otherwise developable residential land.

This could conflict with City goals for residential density, infill development, affordable housing, avoiding urban sprawl, and efficient use of existing streets and utilities. Protecting critical areas and accommodating growth should not be viewed as competing objectives.

Notice to Affected Property Owners

I own a vacant parcel that is substantially affected by the proposed 100-foot requirement. I only became aware of the proposed change about a month ago and learned about it through another individual rather than through direct communication from the City.

I understand that the City has provided public notice through its established process. However, with the City intending to adopt the ordinance in October, affected property owners have very limited time to understand the proposal, evaluate its impact, obtain professional advice, and meaningfully participate.

I respectfully ask the City to identify properties that may be substantially affected and provide those owners with additional notice and a reasonable opportunity to participate before the ordinance is finalized.

Property and Development Impacts

The proposed requirement could have significant consequences for property rights, housing, lot configuration, development costs, and project feasibility.

On my property, the proposed change could materially alter the development potential and configuration, potentially resulting in the loss of 15 residential lots and threatening the economic viability of the project.

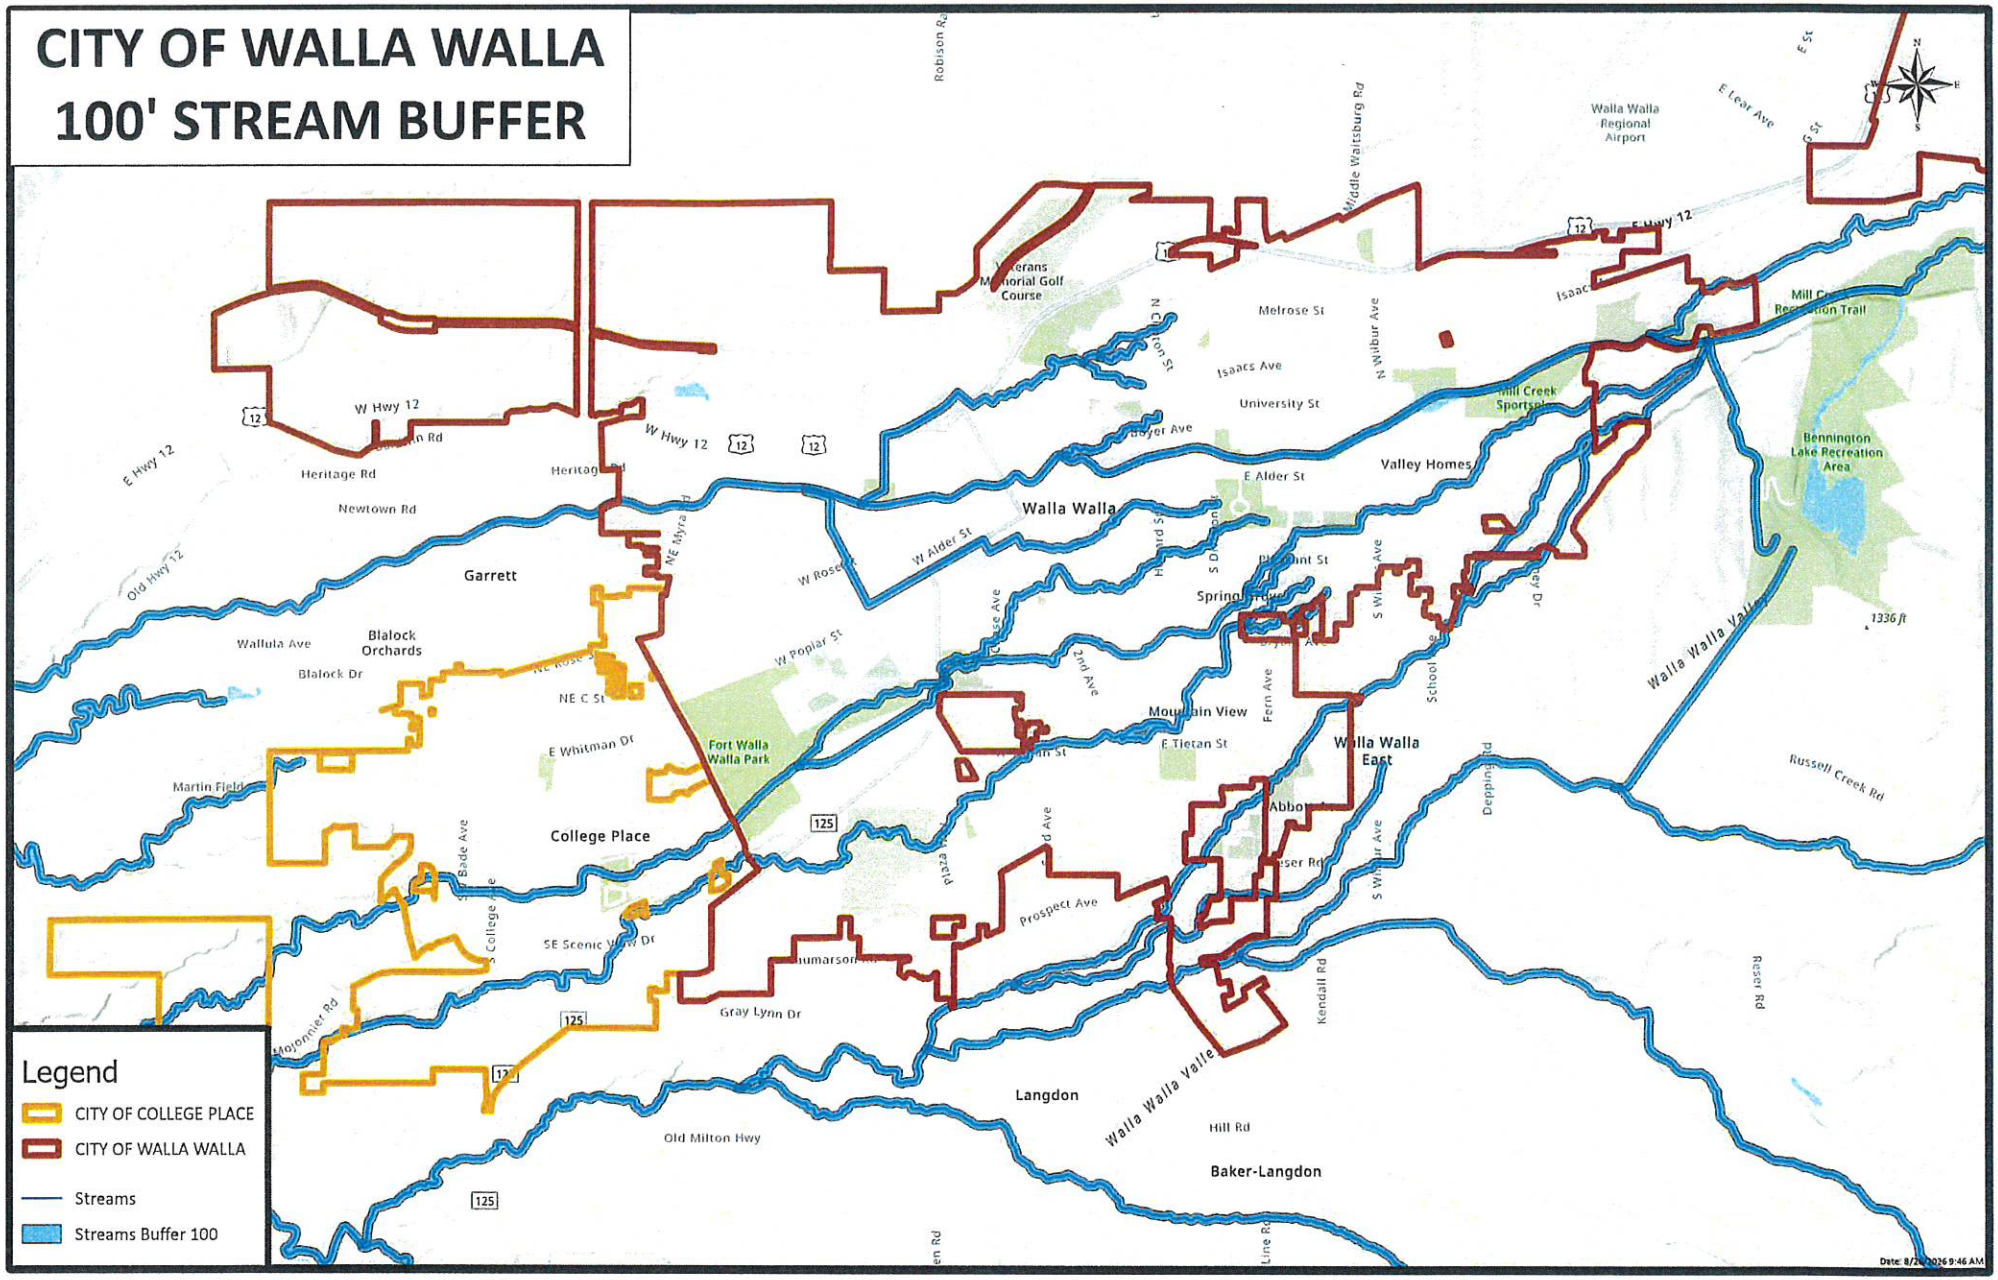
I believe there are reasonable alternatives that could achieve the City's environmental objectives while providing greater flexibility, including:

- Site-specific buffer determinations;
- Buffer averaging;
- Mitigation where appropriate;
- Reasonable provisions for improvements to existing homes; and
- Protections for projects that have already vested or made substantial investments under existing regulations.

Request for Additional Review and Time

I respectfully request that the Planning Commission not recommend adoption of the blanket 100-foot minimum without additional review.

I am not asking the City to weaken environmental protection. I am asking the City to ensure that the regulations follow the science, allow for site-specific evaluation, provide meaningful notice to affected property owners, and balance environmental protection with the impacts on private property, existing homeowners, housing, and development feasibility.



Thank you for your consideration.

Sincerely,

Travis Watts

Opposition to Proposed Critical Areas Ordinance

This letter comes in opposition to the proposed Walla Walla Critical areas ordinance, that will, if approved, will increase properties that have waterways from a 35-foot to 100-foot buffer zone. This proposed buffer zone would infringe on property owners' rights and freedom to what we can or cannot do on our own property.

Serenity Point Counseling Services, LLC, purchased our property in March 2020 with assistance from Washington Department of Commerce via Senate Bill 6248 with the specific goal of expanding behavioral health services in the city and county of Walla Walla.

Our property, 410 S Wilbur Ave., has a portion of Garrison Creek that runs through it. Half of the property is used for our behavioral health services, and the other half is a vacant lot. In 2022, to continue our expansion, the owners of Serenity Point began working with the City of Walla Walla and the Department of Commerce to divide our property in half with the goal of developing sixteen (16) affordable housing units.

Through the City of Walla Walla pre-application process, engineering and architectural services Serenity Point has invested $44,914.50 into our project. As a requirement by the City of Walla Walla, to authorize the dividing of our property line running North to South, Serenity Point was required to construct an east to west public sidewalk along the fenced northern perimeter of our property. With permits, a Bond, construction of the sidewalk and replacing our fence Serenity Point invested another $87,238.76. Finally, after the property division, Serenity Point paid $85,350 to the Department of Commerce plus filing fees to release all interest for the vacant lot portion of the property to Serenity Point. In total Serenity Point has invested $217,503.26 in our goal to create these 16 units.

The property division was finalized on August 24, 2026. The following week Serenity Point Ownership was notified of the proposed critical areas ordinance and were encouraged to schedule another pre-application meeting with City of Walla Walla officials.

At this meeting we were informed that in order keep our project vested under the current ordinances that we would be required to amend our current short plat that will require additional engineering services, an updated SEPA report and as of late last week City officials decided that we would also need to provide a Critical Areas report. All that needed to be completed by and presented by September 15, 2026, to keep our project vested under the current ordinance.

Because of the short turnaround time, the indecisiveness of city requirements for the amended short plat and capital turn around, Serenity Point was unable to meet the September 15 time frame so as a result a change in the proposed ordinance will have a significant and dramatic impact with a reduction of the developmental area of our property and four years of planning,

preparing and investment on our project that would bring much needed affordable housing to our community.

We present this historic overview as an example and emphasize how this proposal to change the current ordinance will impact on us and other property owners that share in the beauty of our property and water ways, if implemented.

In conclusion, we request our City Council to recognize how these proposed critical areas ordinance will infringe on our rights and freedoms and to oppose this change and protect us, the property owners.

Submitted With Respect, on this 21st day of September 2026

Patrick C. Flores, Managing Member
Serenity Point Counseling Services, LLC

To: Members of the Walla Walla City Council
From: James K. Hayner
Date: September 22, 2026
Re: Critical Area Ordinance

I have become quite interested and very concerned about the new proposed Critical Area Ordinance. I appeared and spoke at the public hearing at the Planning Commission. I also participated by zoom in the City Council's recent work session. It is clear to me that the City Planning Department has fully adopted the idea that Walla Walla must utilize 100-foot buffers. The staff has hired a consulting firm which has this same predilection. The city staff seems to have either ignored or avoided considering the significant economic impact that a 100-foot buffer zone would have on the city and its citizens. I believe that the city staff is making a decision more on an ideological basis than one based on what is best for the city, one anchored by the best local science and health of our city's riparian areas.

There are other cities which are refusing to adopt 100-foot buffers as the default, and are either completing their own studies, or making much more flexible methods of using smaller buffer areas. I understand that Bellevue and Kennewick are each adopting a critical ordinance with significant flexibility for landowners. I know that the city of College Place is taking the position that they are very happy with the riparian health around streams and they are not going to adopt a 100-foot buffer. I suspect that there are other cities around the state which are also challenging the 100-foot buffer as it applies to their local jurisdictions.

The Planning Commission recommendation did include a phrase that the city staff should explore the best available science for our local area. But, as was evident at the work session, the city staff paid no heed to the City Planning Commission recommendation and instead has resisted any change or modification from a full 100-foot buffer.

The magnitude of harm by adopting a 100-foot buffer zone in Walla Walla is significant. The city staff identified over 42 miles of riparian water rights. This relates to over 1,100 acres of land. One section of land consisting of 640 acres is one mile square. Now drop two parcels of 1 mile square each on any map of the city of Walla Walla and you will see the significant impact on the city. The study by the consultant indicated that the buffers adopted by the city should have no net loss of riparian area from any prior buffers. In fact, the consultant has opined that by adopting a 100-foot buffer in Walla Walla, there would be a 70% gain of riparian areas. This means that of the 1,100 acres affected by such a 100-foot buffer, 700 to 800 acres will be directly affected by the buffer such that development on those properties will be impaired or disallowed.

As Councilman Eskil explained, Walla Walla has been developing for over 150 years along riparian waterways. It has been the consensus of residents of the city that they have done so in an environmentally sensitive manner. Riparian buffers have provided adequate safeguards to our many streams. Expanding the riparian buffer significantly will have no tangible benefit, but will in fact produce significant harm to our citizens and their property. We do not believe that there has been any harm to the riparian waterways. Many houses are built close to streams.

The Walla Walla zoning code is primarily based upon R-96 zoning around the city. This means that the minimum lot size is 9,600 square feet. Many lots meet the minimum and are approximately 100x100. Thus, for any undeveloped lot in the R-96 zone that is 100x100 and that has a stream that touches any portion of that lot, it would now be undevelopable and unbuildable. The city's zoning policy expresses an interest of having at least 4 lots per acre. With the new 100-foot buffer that is going to be virtually impossible. Lot sizes are going to have to increase dramatically. Density is going to be reduced as opposed to increased. The Comprehensive Plan suggests that Walla Walla should reply upon infill and more density. These goals are absolutely impossible with a 100-foot buffer zone for the entire city.

Councilman Outlaw asked the question as to what would happen to existing homes if the owners want to build additions. I believe the answer he received was disingenuous. The obvious answer is that unless that house has the ability to adhere to a new 100-foot buffer and the new and larger setbacks, no change will be allowed. No extra room could be added, there would be no ADU allowed, there would be no new patio. Furthermore, there is a question as to what might happen if a house were to burn to the ground. I suspect that they would only be able to rebuild in exactly the same footprint as the original house, and they would be denied the right to utilize any different footprint that encroached closer to the water than the existing footprint. Furthermore, there is a question as to how long this grandfather right would exist. If a house were burnt to the ground and the residents were not capable of rebuilding within a relatively short period, is the grandfather right to rebuild forfeited?

The city staff continues to put emphasis on the best scientific evidence. The state has rolled out a very long report developed over a period of nine years. Remember that this report was developed under the direction of Governor Inslee who has been one of the most aggressive environmentally protective Governors in the country. If you remember, he ran for a short period of time for President on a very environmental protective platform. Even though this report took nine years, the conclusion was predetermined. However, the question is whether that report actually covers the best scientific evidence for every locale in the state. I do not believe it does. Furthermore, I do not believe that there is one best scientific conclusion. I offer as an example the decades of controversy over protecting salmon in the Columbia and Snake Rivers. There have been dozens of best scientific evidence reports which have come to diametrically opposed conclusions. If you go to several medical doctors and ask for the best scientific evidence as to treatment you will get a variety of opinions. I think it is both possible and important that the city develop its own best scientific evidence for purposes of the Critical Area Ordinance.

The city staff argues that developing its own ordinance will be a lot of work and will cost hundreds of thousands of dollars. They may be right. But by unilaterally adopting a 100-foot buffer they have chosen to ignore the millions of dollars of economic loss that the city will incur and landowners will incur in loss of property value.

At the Planning Commission hearing two different landowners testified that they had parcels of land of about 6 acres each. They plan to subdivide that land. Each one has a stream running through the property. Nevertheless, based upon current setbacks they could meet the city's goal of four houses per acre and each of the subdivisions would have about 25 lots. Both of those landowners indicated that with a 100-foot buffer, their property now becomes undevelopable for

housing. Just in those two parcels, the city will lose 50 lots. If those lots have a conservative value of $100,000 each, that is $5M taken out of the tax base. Now assume that those lots were all developed with average price level homes of $500,000. You have now taken out of the tax base $25M. Also assume that to develop those houses there is substantial sales tax being generated of several million dollars. Therefore, in just these two parcels of 12 acres the city will lose over $30M in tax base and/or actual taxes paid during construction. That land will likely never be able to be developed and will become virtually useless. And this is only 12 to 13 acres of the 700 acres that will be adversely affected by a 100-foot buffer zone.

Every landowner who has land that is affected will have a legitimate claim that the value of their land has been significantly reduced for tax purposes. Furthermore, landowners are likely to assert claims and/or lawsuits on the basis that they have incurred actual damages by the inverse condemnation of their property by the city. The economic detrimental effect could be hundreds of millions of dollars as compared to a couple hundred thousand dollars in developing a local best scientific evidence report. The city could choose carefully to make sure that the consultant used is practical in nature and has a bias for smaller buffer areas.

I do not think it is out of the realm of possibility that many landowners, developers, realtors, and citizens would happily contribute to a fund to develop best science for our local area which proved that our riparian areas were healthy with a 35-foot setback and we do not need a 100-foot setback.

The proposed Critical Area Ordinance overrides all of the city's efforts for lot infill, higher density, and affordable housing.

City attorney Tim Donaldson argues that if the city does not adopt this mandated 100-foot buffer, that it may not be eligible for certain state grants. Assuming that Tim is correct, the city still has to weigh the loss of those grants against the significant economic impact of the 100-foot buffers. The city needs to study this more carefully, taking into account all of the various consequences and impacts before it unilaterally accepts a report that only reflects one view of the scientific evidence.

City of Walla Walla - 2026 Critical Areas Ordinance Update

Technical, Legal, and Policy Concerns Raised by Walla Walla's Draft Critical Areas Ordinance

Questions the record should answer before adoption.

Technical, legal, and policy review of the proposed replacement of the City's differentiated riparian buffers with a uniform 100-foot minimum standard and the supporting record.

SUBMITTED TO
City of Walla Walla City Council

MATTER
2026 Critical Areas Ordinance Update
File PLN5-26-0001

SUPPORTING RECORD
Planning Commission and 2026 CAO proceedings

PREPARED BY
Matt Heuer, Government Affairs Director
Walla Walla Valley Association of REALTORS®

WALLA WALLA VALLEY
ASSOCIATION OF REALTORS®

Purpose

These concerns relate primarily to the proposed replacement of Walla Walla's existing differentiated 35-foot and 50-foot riparian buffers with a uniform 100-foot minimum buffer for most open streams regulated under the City's Critical Areas Ordinance.

There is no dispute that Walla Walla must protect critical areas. There is no dispute that the City must include Best Available Science, or BAS, when developing its regulations. There is also no dispute that WDFW recommends substantial riparian protection and generally recommends a 100-foot minimum RMZ in dryland settings when the pollution-removal function controls.

The questions are different:

Has the specific choice of a uniform 100-foot standard been accurately represented as legally required? Has the City adequately examined Walla Walla's local conditions? Has it evaluated reasonable alternatives? Has it demonstrated why the existing differentiated system is inadequate? Has it reconciled the proposed regulation with other GMA and Comprehensive Plan obligations? Does the City understand the ramifications of the proposed 100-foot buffer? And has it created a sufficiently complete record to support the policy choice it is asking elected officials to make?

The available record raises substantial concerns on each of those questions.

On September 14, 2026, the Planning Commission declined to recommend the draft CAO as presented and instead unanimously recommended that City Council direct staff to revise the ordinance to better align with the Comprehensive Plan and local needs. This review is submitted to inform the Council's consideration of that recommendation.

Contents

01 Washington law does not mandate a 100-foot riparian buffer

02 Labeling the proposal 'State Mandated' obscures the distinction between state law and local policy choice

03 WDFW expressly distinguishes its science from its policy recommendations

04 WDFW expressly recommends site-specific RMZ determinations and warns against one-size-fits-all widths

05 The City has not performed an alternatives analysis showing why other approaches are inadequate

06 The Facet memorandum is a GIS planning analysis, not an ecological efficacy study

07 The City has not demonstrated that its existing differentiated system is failing

08 Walla Walla's own evidence shows materially different conditions, yet the proposal imposes one answer

09 WDFW selected a pollutant-removal target; the City has not shown it independently selected that target

10 The proposal expands regulated land dramatically without quantifying the incremental ecological benefit

11 Much of the proposed buffer is already developed, impervious, or functionally disconnected

12 The proposal blurs the distinction between mandatory protection and desired restoration

13 The record does not show how the City balanced environmental protection with other GMA goals

14 Housing-capacity and infill consequences have not been quantified

15 Consequences for existing lawful homes and lots remain insufficiently defined

16 Discretionary relief does not erase the burden created by the underlying regulation

17 The SEPA record should be revisited in light of the documented scale of the change

18 Other Washington jurisdictions show that BAS can support a documented, differentiated approach

19 The City's description of a 'separate analysis' is inconsistent with the record produced

20 Recommended Corrective Action

01 Washington law does not mandate a 100-foot riparian buffer

RCW 36.70A.172 requires cities and counties to include Best Available Science when developing policies and development regulations protecting the functions and values of critical areas. It also requires special consideration of measures necessary to preserve or enhance anadromous fisheries.

RCW 36.70A.060 requires adoption of development regulations protecting critical areas.

Neither statute prescribes a 100-foot buffer.

WAC 365-195-915 further recognizes that a jurisdiction may depart from a science-based recommendation when the record identifies the information relied upon, explains the rationale, identifies the risks associated with the departure, and explains measures used to address those risks.

> CONTENTION
> **The state mandates a result - protection of critical-area functions through regulations developed using BAS. It does not mandate WDFW's preferred 100-foot regulatory response.**

02 Labeling the proposal 'State Mandated' obscures an important distinction between state law and local policy choice

The City's staff materials repeatedly categorize significant CAO amendments as 'State Mandated' under RCW 36.70A.172.

The staff report explains the BAS requirement and then states:

> **"To this end, the riparian buffer zones on either side of the City's creeks and streams are proposed to increase from 35 or 50 feet...to 100 feet."**

That presentation collapses two separate decisions:

- the Legislature's requirement that the City include BAS and protect critical-area functions; and
- the City's decision about which local regulation to adopt after applying that science.

> CONTENTION
> **Decision-makers should be expressly told that 100 feet is a City policy choice informed by a WDFW recommendation, not a buffer width imposed by RCW 36.70A.172.**

That distinction matters because elected officials may reasonably evaluate a supposed state mandate differently than a local legislative choice.

03 WDFW expressly distinguishes its science from its policy recommendations

This distinction is not an interpretation offered by opponents of the ordinance. WDFW says it itself.

Volume 1 states that Volume 2's management guidance is:

> **"not in and of itself 'best available science.'"**

Instead, Volume 2 represents WDFW's recommendations for how local governments could incorporate BAS into policies, plans, and regulations.

Volume 2 repeats the point even more directly:

> **"The information presented in this management recommendation document is not, in and of itself, science. Rather, it consists of policy recommendations which are informed by the best available science..."**

Volume 2 also describes WDFW's role in Washington land-use decision-making as that of 'advisor,' working with decision-makers and landowners to accommodate both human needs and fish and wildlife needs.

This distinction is especially important because City staff itself has acknowledged Volume 1 as the BAS source and Volume 2 as management guidance.

> CONTENTION
> **The City should not treat WDFW's recommended implementation policy as though the recommendation itself were synonymous with BAS or a statutory mandate.**

04 WDFW expressly recommends site-specific RMZ determinations and warns against one-size-fits-all widths

Volume 2 contains one of the clearest statements relevant to Walla Walla's proposal:

> **"Establish RMZ widths based on site-specific conditions."**

WDFW explains that riparian ecosystem width varies with ecological conditions and states that the most efficient protection recognizes those differences rather than adopting uniform-width, one-size-fits-all RMZs, because uniform standards can produce over-protection in some locations and under-protection in others.

WDFW also cautions that Volume 2 contains statewide recommendations and does not address unusual site-scale environmental conditions or issues specific to particular ecological communities. It strongly encourages those issues to be addressed locally with WDFW regional habitat biologists, technical experts, tribes and other stakeholders.

WDFW's comments on Walla Walla are consistent with that guidance: although it stated that 100 feet 'may be compliant,' it also indicated that site evaluation would be preferable for determining the correct width.

CONTENTION

WDFW's own management guidance does not support treating statewide guidance as a substitute for evaluating materially different local stream conditions.

05 The City has not performed the alternatives analysis that would demonstrate why other approaches are inadequate

The July 1 Facet memorandum compares the mapped footprint of only two regulatory scenarios:

- Walla Walla's existing 35/50-foot framework; and
- WDFW's 100-foot dryland RMZ scenario.

It does not evaluate the ecological performance of the existing buffers, nor does it evaluate:

- 60-foot buffers;
- 75-foot buffers;
- revised reach-specific standards;
- different treatment of different stream types;
- narrower buffers combined with native vegetation enhancement;
- stormwater treatment;
- low-impact development;
- habitat connectivity improvements;
- differentiated treatment of heavily developed or functionally disconnected reaches; or
- packages combining multiple protective measures.

Facet therefore does not establish that reasonable alternatives fail to protect required functions.

CONTENTION

Comparing the mapped footprint of the existing ordinance with one preferred regulatory alternative is not the same as evaluating the existing ordinance or modeling meaningful alternatives and demonstrating why they are insufficient.

06 The Facet memorandum is a GIS planning analysis, not an ecological efficacy study

Facet's work is valuable for understanding the geographical consequences of changing the ordinance.

It identifies streams, overlays buffer scenarios, examines impervious surfaces, and estimates functionally disconnected areas.

But Facet expressly states that its analysis is appropriate for broad-scale planning and 'should not be used for site-level determinations.'

It therefore answers:

> **"How much land will fall inside the regulatory area if the City adopts 100 feet?"**

It does not answer:

"What width is necessary on each Walla Walla stream or reach to protect the functions actually present there?"

CONTENTION

The City's principal technical study quantifies the footprint of the proposed policy. It does not establish the ecological necessity of that policy.

07 The City has not demonstrated that its existing differentiated system is failing

Walla Walla already regulates these waterways.

The existing ordinance identifies specific streams and reaches, their characteristics, targeted ecological functions, existing riparian widths and different regulatory buffers.

For example, the existing record distinguishes Yellowhawk Creek from Russell Creek and Reser Creek based upon fish use, downstream influence, shade, woody debris, vegetation and other characteristics.

Volume 2 makes the absence of a performance analysis more significant. WDFW specifically recommends implementation and effectiveness monitoring to determine whether existing regulations are actually producing intended environmental outcomes such as shade and bank stability.

The current record does not appear to identify:

- which functions are presently being lost under Walla Walla's existing buffers;
- on which reaches those losses occur;
- whether existing permit implementation is failing;
- whether violations rather than buffer width are causing failures; or
- what monitoring demonstrates that the existing standards cannot protect those functions.

CONTENTION

Before replacing an existing BAS-derived differentiated system with a dramatically more restrictive system, the City should identify what is failing and demonstrate how the proposed regulation corrects that failure.

08 Walla Walla's own evidence demonstrates materially different conditions, yet the proposed ordinance imposes the same answer

The City's existing information identifies average riparian widths of approximately:

- Yellowhawk: 31 feet
- Russell: 21 feet
- Reser: 23 feet
- Stone: 20 feet
- Garrison: 24 feet
- Bryant: 14 feet
- Titus: 25 feet

Those waterways also differ in fish use, channelization, vegetation, surrounding development, hydrology, downstream influence and existing ecological function.

The City's existing reach-based table itself reflects those differences. Yellowhawk is identified for summer steelhead migration and limited rearing habitat, while other reaches are identified for differing combinations of downstream influence, stormwater and pollutant control, wildlife habitat, shade, woody debris and existing riparian conditions.

Nevertheless, the proposed Table 6 places nearly all open streams into the same 100-foot minimum category.

CONTENTION

The City's own evidence demonstrates ecological heterogeneity. WDFW says site-specific differences matter. A uniform regulatory answer therefore requires a persuasive local explanation that does not presently appear in the record.

09 WDFW selected a policy target for pollutant removal, but the City has not demonstrated that it independently selected that target for Walla Walla

This is an important distinction.

Volume 1 states:

> **"Riparian buffer width recommendations depend on the particular pollutant to be removed and the desired removal efficacy. Policy makers must choose the desired removal efficacy."**

WDFW's Volume 2 then makes its management recommendation. Where SPTH or riparian vegetation is less than 100 feet, WDFW recommends a 100-foot minimum intended to achieve approximately 95% removal for most pollutants, although it notes approximately 85% for surface nitrogen.

Those are two different propositions:

- The science describes how performance changes with width.
- WDFW then recommends a particular policy target.

The Jacobs memorandum for Enumclaw illustrates this directly. It reproduces the WDFW/Quinn pollutant-removal data at different performance levels and states that the amount of pollutant removal desired is a community choice.

CONTENTION

WDFW has made its policy recommendation. The City's record should demonstrate why Walla Walla independently concluded that WDFW's selected performance target is appropriate for every regulated urban stream.

10 The proposal expands regulated land dramatically without quantifying the corresponding incremental ecological benefit

Facet estimates that the current buffer system encompasses approximately 268.8 acres.

Under the 100-foot scenario, that becomes approximately 757.4 acres.

The mapped buffer footprint therefore increases by approximately 489 acres, nearly tripling the regulated area and increasing it from roughly 2.1% to 5.8% of the study area.

What the analysis does not calculate is the corresponding incremental ecological gain. For example:

- How much additional sediment removal occurs?
- How much additional nitrogen removal occurs?
- How much additional shade results?
- Which reaches gain meaningful habitat connectivity?
- Which additional acreage contributes woody debris?
- Which acreage performs little or no present riparian function?
- How much of the approximately 489-acre expansion is already developed private property?
- What incremental habitat or water-quality improvement is expected on already-developed parcels if existing lawful development remains in place?

CONTENTION

A large regulatory expansion should be supported by analysis of what additional ecological performance the additional regulated acreage actually purchases.

11 The City's own analysis shows that a substantial portion of the proposed buffer is developed, impervious, or functionally disconnected

Under the 100-foot scenario, Facet finds approximately 30.4% of the mapped area to be impervious or functionally disconnected.

Facet also acknowledges that the expanded buffers reach developed parcels, roads and other land uses that may not presently provide riparian function.

Even Facet's 'vegetated' category includes lawns, parks, fields and managed open space, rather than only functioning native riparian vegetation.

The record does not separately quantify how much of the approximately 489-acre expansion consists of already-developed parcels, nor how much additional ecological function the ordinance is expected to produce on those parcels. Workshop discussion also indicated that existing developed property owners would not simply be required to restore habitat because the regulatory line moved.

Volume 2 adds important nuance. WDFW warns that impervious surfaces and untreated stormwater can themselves alter peak flows, channel form and pollutant removal. That supports a broader regulatory analysis rather than simply treating impervious land as irrelevant.

CONTENTION

In developed urban watersheds, the appropriate question is not merely 'How wide is the line?' The City should evaluate whether combinations of buffer protection, stormwater treatment, infiltration and pollutant removal, low-impact development, vegetation enhancement and other measures more effectively address the actual functions and impairments present.

12 The proposal blurs the distinction between mandatory protection and desired restoration

WDFW strongly favors both protection and restoration.

Volume 2 acknowledges that historical development has degraded riparian systems and states that WDFW believes remaining intact habitat alone is insufficient to provide the full functions fish and wildlife need. WDFW consequently recommends restoration where possible.

But WDFW also distinguishes restoration from protection. Volume 2 describes voluntary restoration actions, and Volume 1 expressly notes that the planning, regulatory and legal contexts governing protection and restoration differ.

Washington's Swinomish decision likewise recognizes that the GMA's duty to protect existing critical-area functions is not automatically equivalent to a mandate to restore historically lost functions.

CONTENTION

Where the proposed 100-foot area extends across developed urban land that no longer provides full riparian function, the City should identify whether the regulation is protecting existing function, preventing a new loss, mitigating a proposed impact, or attempting to restore a function that is presently absent. Those purposes may support different regulatory tools and different legal analyses.

13 The supporting record does not demonstrate how the City balanced environmental protection with other GMA and Comprehensive Plan objectives

The GMA contains multiple planning goals, including environmental protection, housing, property rights, urban growth, economic development, permit predictability and citizen participation.

Those goals are not ranked by RCW 36.70A.020.

Walla Walla's own 2046 Comprehensive Plan calls for:

- infill development;
- housing choice;
- accessory dwelling units;
- efficient use of existing infrastructure;
- additional residential development; and
- evaluation of the effects of development regulations.

WDFW itself recognizes this balancing process. Volume 1 states that natural-resource and land-use policies must often balance ecological, economic and social goals, and that determining an acceptable balance requires a political process involving stakeholders, local governments, tribes and state agencies.

Volume 2 likewise acknowledges that human needs must be incorporated into land-use decision-making.

CONTENTION

The City should demonstrate the balancing exercise the GMA, the Comprehensive Plan and WDFW's own framework contemplate. The existing record fails to do this.

14 Housing-capacity and infill consequences have not been quantified

Facet establishes that the proposed 100-foot standard expands the mapped buffer footprint by nearly 489 acres.

The available record does not appear to quantify:

- affected buildable acreage;
- housing units potentially foregone;
- infill parcels constrained;
- redevelopment capacity affected;
- reductions in building envelopes;
- interaction with the City's housing-capacity analysis;
- impacts on the assumptions underlying Walla Walla 2046; or
- economic effects on affected property.

The concern was independently raised in public comments, including Howard Boggs' observation that many stream-adjacent areas are already developed and that substantially larger buffers could reduce future infill opportunities.

CONTENTION

The City should know whether a regulation affecting hundreds of additional urban acres conflicts with the growth and housing assumptions on which its newly adopted Comprehensive Plan depends.

15 The consequences for existing lawful homes and lots remain insufficiently defined

Many affected properties were developed before the adoption of current critical-area setback requirements or under substantially different regulatory standards. The proposed 100-foot standard will place many of those existing homes and lots inside a newly expanded regulatory area.

Questions raised in the public record include:

- Can an existing home be rebuilt after a fire?
- Can an owner build a second story?
- Can a garage be added?
- Can a deck or patio be constructed?
- What happens to an undeveloped legal lot?
- What rights attach to recorded plats?
- What happens to pending applications?
- How are additions treated?

A practical question for existing owners	How does any new nonconforming status affect resale, insurance, financing or marketability?

These are not abstract issues. They determine the practical effect of the ordinance on existing lawful property owners.

CONTENTION

A major citywide regulatory amendment should clearly establish the rights retained by existing owners rather than requiring those answers to emerge later through individual administrative interpretations.

16 Discretionary relief does not erase the burden created by the underlying regulation

The draft contains several mechanisms that may modify the standard buffer in particular circumstances. Those provisions are important, but they are not equivalent to an unaffected property right.

Functionally disconnected areas. Where impervious surfaces or lawfully established structures disconnect the buffer from the stream, the Director may approve a complete or partial modification to exclude non-functional areas.

Buffer averaging. The draft allows portions of a buffer to be narrowed, but the total area after averaging must equal the area required without averaging and the narrowest point may not be less than 75% of the standard width. On small, already-developed parcels, there may be little or no practical room to move the displaced buffer elsewhere.

Decreased buffer widths. A separate case-by-case provision allows the Director to approve a reduction when specified criteria are satisfied. For a 100-foot standard, Table 7 identifies a potential reduction to 75 feet with approved habitat enhancement or water-quality treatment.

To obtain relief, a property owner may still be required to:

- retain a qualified professional;
- prepare a critical-area report;
- establish existing ecological conditions;
- demonstrate satisfaction of regulatory criteria;
- prepare habitat enhancement;
- address water quality;
- conduct monitoring; and
- obtain discretionary Director approval.

The applicant bears the cost of the professional studies, documentation, enhancement planning, monitoring and administrative process necessary to establish eligibility for relief.

The required enhancement plan must identify existing conditions, demonstrate improved riparian function and include a five-year monitoring program.

> CONTENTION
> **The existence of discretionary modification or relief mechanisms does not mean a property is unaffected. Cost, delay, uncertainty, professional studies and administrative discretion are regulatory impacts themselves, and those burdens are borne by the property owner.**

17 The SEPA record should be revisited in light of the scale of the regulatory change now documented

The City's SEPA materials state that the proposed amendments are not expected to create significant adverse impacts.

However, the available SEPA discussion does not appear to analyze the approximately 489 additional acres subsequently identified by Facet, nor does it quantify effects on housing capacity, infill, redevelopment or existing lawful development.

This does not establish that the City's SEPA determination is invalid. It does create a legitimate record question:

> **"Did the environmental review adequately consider the probable land-use consequences of the specific regulatory proposal ultimately advanced?"**

> CONTENTION
> **Before final adoption, the City should determine whether the Facet acreage findings and resulting development consequences warrant supplemental or additional SEPA consideration.**

18 Other Washington jurisdictions demonstrate that BAS can support a documented, differentiated local approach

Enumclaw provides a useful example, but it should be described accurately.

Jacobs' BAS memorandum did not recommend that Enumclaw simply disregard WDFW's guidance.

At the time of the Jacobs analysis, Enumclaw had:

- Type S: 100 feet
- Type F: 75 feet

- Type Np: 50 feet
- Type Ns: 25 feet

Jacobs concluded that Type S was consistent with WDFW's local SPTH analysis, recommended considering an increase in Type F to 100-105 feet, and recommended reconsideration of Np and Ns widths. Significantly, Jacobs did not simply recommend converting every stream to 100 feet. For Type Ns, it specifically discussed increasing the width enough to achieve at least 80% pollutant removal, depending on adjacent land uses and buffer quality.

Jacobs also recommended evaluating baseline conditions, protecting remaining functions, enhancing degraded areas, maintaining connectivity and using complementary management practices.

Enumclaw ultimately adopted differentiated stream standards in 2025:

- Type S: 100 feet
- Type F: 100 feet
- Type Np: 60 feet
- Type Ns: 30 feet

WDFW objected during that process that the Np and Ns widths remained below its recommended 100-foot minimum.

The value of Enumclaw as an example is therefore not that its numbers should be copied by Walla Walla, nor that its ordinance has somehow been judicially declared valid. The lesson is that another Washington city commissioned a signed BAS analysis, examined local conditions and functions, received WDFW's 100-foot recommendation, considered it, and nevertheless adopted a differentiated local regulatory framework.

Kennewick provides an eastern Washington example. Kennewick's 2026 BAS review, prepared with Parametrix, identified WDFW's 100-foot dryland RMZ recommendation and recommended considering at least 100 feet for non-fish-bearing streams. Kennewick nevertheless retained a differentiated local framework, including 75-foot Type F and 50-foot Type N stream buffers, together with habitat assessment, buffer-averaging and functionally disconnected-area provisions.

> **CONTENTION**
> **Walla Walla can engage the same science without treating one statewide recommendation as the only legally available outcome. What matters is the quality of the local record supporting the choice.**

19 The City's description of a 'separate analysis' is materially inconsistent with the technical record produced in response to the public-records request

Deputy Director Emily Arteche advised that the City had completed a separate analysis outside the ordinance work and that the results demonstrated alternative setback buffers 'could not provide better protection for the riparian management zone.'

That statement indicated that alternatives had actually been evaluated and rejected based on technical analysis.

A public-records request was therefore submitted seeking:

- that analysis;
- supporting consultant work;
- technical reports;
- GIS information;
- maps; and
- related supporting records.

The City closed the request after producing the July 1 Facet memorandum, the September Planning Commission PowerPoint and directing the requester to the August 3 Facet presentation.

The Facet memorandum does not contain the finding described. It compares the mapped footprint of the existing 35/50-foot regulatory framework with the 100-foot WDFW scenario. It does not evaluate the ecological performance of the existing buffers, analyze 60 feet or 75 feet as alternatives, evaluate revised reach-specific standards, or test combinations of narrower buffers and complementary measures. It does not conclude that those alternatives fail. It does not conclude that alternative setbacks 'could not provide better protection.'

The discrepancy therefore leaves two possibilities:

Either additional responsive analysis exists and was not produced, or the analysis was characterized to the requester as materially more extensive and conclusive than the record actually demonstrates.

> **CONTENTION**
> **Before elected officials rely upon the assertion that alternatives were studied and rejected, the City should identify the specific analysis supporting that statement and place it in the legislative record.**

20 Recommended Corrective Action

There are a number of lawful approaches the City could take to address these concerns. The following is one recommended path, not the only solution. The goal is not to substitute another arbitrary number for 100 feet, but to complete the analysis necessary to determine the appropriate regulation for Walla Walla.

The City should consider:

1. Pause final adoption of the uniform 100-foot riparian-buffer amendments.

2. Request written guidance from the Washington Department of Commerce regarding the December 31 periodic-update deadline, procedural options available to the City, and application of the statutory substantial-progress provisions.

3. Commission qualified ecological professionals to perform a reach-by-reach analysis of Walla Walla's streams.

4. Establish baseline existing conditions and identify the ecological functions presently occurring on each reach.

5. Evaluate meaningful candidate buffer widths and their expected performance.

6. Evaluate complementary measures including native vegetation enhancement, stormwater treatment, infiltration and pollutant removal, low-impact development, connectivity improvements and other mitigation.

7. Distinguish protection of existing ecological function from restoration of degraded or absent functions.

8. Quantify housing, infill, redevelopment and existing-property impacts, and clearly establish owners' rights, nonconforming-property treatment and administrative standards.

9. Build the written BAS record necessary to explain the City's eventual decision, including the risks associated with any departure from a scientific recommendation and the measures used to address those risks.

10. Incorporate monitoring and adaptive management, consistent with WDFW's own recommendation that local governments measure whether regulatory requirements are actually producing intended ecological outcomes.

11. Return the completed analysis to the Planning Commission, City Council and public before final adoption.

The Association recognizes that this work may require additional funding, staff capacity and time. Those practical constraints should be identified and weighed openly as part of the legislative decision rather than substituted for the technical and policy analysis itself.

Walla Walla does not appear to qualify for the GMA's automatic 24-month small-jurisdiction extension. However, RCW 36.70A.130 provides limited treatment for jurisdictions fewer than 12 months out of compliance with the periodic-update deadline for critical-area development regulations as making substantial progress toward compliance for specified state financial-eligibility purposes.

That provision is not an extension of the legal deadline and does not eliminate litigation risk.

It does demonstrate that state law contemplates circumstances in which a jurisdiction may continue completing critical-area regulations after the periodic-update date rather than treating December 31 as justification for adopting an inadequately developed regulatory record.

The City should therefore obtain written Commerce guidance before deciding that schedule pressure requires immediate adoption.

THE STANDARD FOR COMPLETING THIS WORK IS STRAIGHTFORWARD

Show the work.

If a reach-specific analysis demonstrates that a 100-foot buffer is necessary to protect the required functions of Yellowhawk Creek or another waterway, the City should have a defensible basis for adopting 100 feet there. If another reach can protect its required functions using a narrower buffer combined with stormwater treatment, native vegetation enhancement, mitigation or other protective measures, the City should have the scientific and legal record necessary to support that decision as well.

The objective should not be the largest buffer. It should not be the smallest buffer. The objective should be the locally appropriate, scientifically supportable and legally defensible buffer.

Respectfully submitted,

Matt Heuer

FACET

City of Walla Walla - Stream Buffer Analysis

Date:	July 1, 2026
To:	Emily Arteche, Jon Maland - City of Walla Walla, Development Services
From:	Sam Payne, Ecologist & Wildlife Biologist; Nell Lund, Senior Ecologist
Project Name:	Walla Walla CAO Update – Stream GIS Analysis
Facet Number:	2507.0393.01

1. Introduction

This technical memorandum summarizes the results of a spatial analysis conducted to inform the City of Walla Walla's evaluation of potential riparian management zone (RMZ) modifications as part of the critical areas ordinance update. The analysis compares the City's existing stream buffer framework with a dryland RMZ scenario based on current guidance from the Washington Department of Fish and Wildlife (WDFW). The evaluation also considers the extent of impervious surface and functionally disconnected buffer areas within each scenario to support a planning-level understanding of potential regulatory and ecological implications.

In 2020, WDFW published a synthesis of the best available science for riparian ecosystems (Quinn, Wilhere, and Krueger 2020), followed by management recommendations that support a shift from regulating stream buffers to regulating RMZs (Rentz et al. 2020). Although RMZs are conceptually and practically similar to stream buffers, they are intended to protect the broader ecological functions provided by riparian ecosystems, including water quality protection, stream shading, habitat connectivity, pollutant removal, bank stability, and other functions beyond direct stream habitat.

While much of WDFW's RMZ framework is based on site potential tree height (SPTH), dryland ecosystems, including those in the City of Walla Walla, are addressed through a simplified dryland RMZ framework. Under that framework, open streams are assigned a minimum 100-foot water quality buffer, which may be expanded where the surrounding riparian vegetative community extends farther. For this analysis, piped stream segments were assumed to have no buffer, and Shorelines of the State were excluded because they are regulated under the City's Shoreline Master Program.

2. Methods

2.1 DATA ACQUISITION

To compare the recommended RMZs with existing stream buffers, available GIS data were processed to create stream, buffer, and RMZ layers for each scenario within the City of Walla Walla. The following data types were collected and processed for this analysis.

Table 1. Data, sources, and purposes in this analysis

Data Type	Data Source	Purpose
Streams Shapes *Received 2026*	City of Walla Walla Streams Layer, including intermittent streams	Stream centerlines used for buffer scenarios
Stream Typing *Received 2026*	City of Walla Walla CAO	Buffers distances determined by stream-specific ordinances
Riparian-related Data *Received 2026*	City of Walla Walla (USGS and USFW)	Used to create existing riparian areas. NHD Waterbody, NHD Major Areas, Washington Riparian Areas, and Washington Wetlands were sent by the City of Walla Walla, sourced from the USGS National Hydrography dataset and from the USFW National Wetlands Inventory
City Limits *Received 2026*	City of Walla Walla	Used as a study area
Impervious Surface *Received 2026*	City of Walla Walla	Used to evaluate development implications of potential RMZs

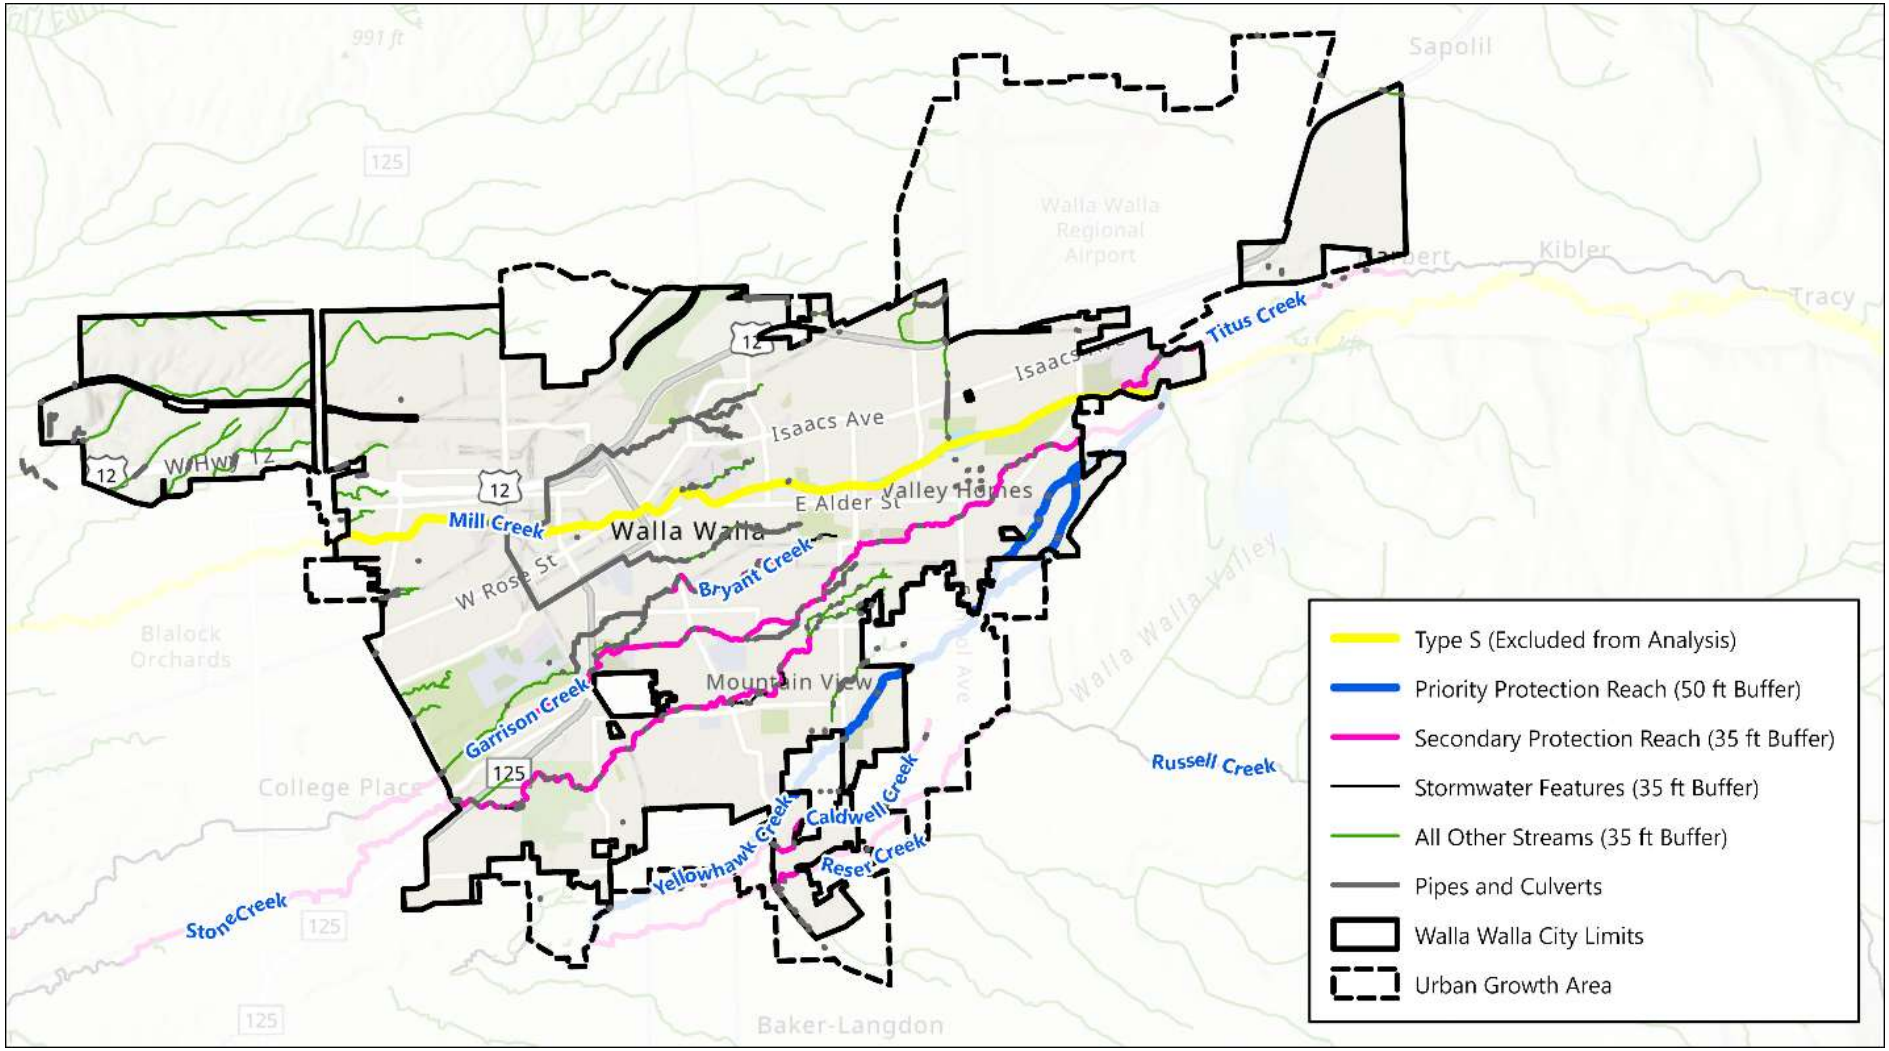

Figure 1. Walla Walla streams mapped by existing CAO criteria

2.2 ALTERNATIVE SCENARIOS

Two alternative scenarios were evaluated which include (1) the current regulatory environment, and (2) dryland RMZs aligning with recommendations by WDFW (Rentz et al. 2020).

Under the current regulatory framework in Walla Walla Municipal Code (WWMC) 21.04, Critical Areas, streams are assigned fixed-width buffers based on the established buffer width for each defined reach. The current framework includes 50-foot buffers for designated *priority protection reaches*, 35-foot buffers for other designated streams (referred to as *secondary protection reaches* for the purpose of this analysis), and 35-foot buffers for all other regulated streams. Piped stream segments are not subject to buffer requirements.

WDFW's dryland ecosystem RMZ recommendations establish a 100-foot water quality buffer, which may be expanded to include the full extent of the surrounding riparian vegetative community. Based on the average riparian vegetation widths identified in WWMC 21.04.650, none of the evaluated reaches exceeds the 100-foot RMZ; however, localized areas within the city may warrant wider buffers where riparian vegetation extends beyond 100 feet (Table 2). For purposes of this analysis, piped stream segments are assumed to have no buffer.

Table 2. Walla Walla streams and current buffers, and average width of riparian vegetation according to WWMC 21.04.650.

Stream	Existing Buffer (ft)	Existing Riparian Average from City (ft)
Mill Creek *From Gose Street to Bennington Lake dam diversion*	SMP managed stream, not included in analyses	Not applicable
Yellowhawk Creek *Russell Creek to Mill Creek*	50	31
Russell Creek *Dipping Road to Yellowhawk Creek*	35	21
Reser Creek *Wilbur Avenue to Russell Creek*	35	23
Caldwell Creek *Headwaters to Yellowhawk Creek*	35	None listed
Stone Creek *Headwaters to Teal Street*	35	20
Garrison Creek *Yellowhawk Creek to Lions Park (excluding wetland)*	35	24
Bryant Creek *Sprague Avenue to Fort Walla Walla Park*	35	14

Stream	Existing Buffer (ft)	Existing Riparian Average from City (ft)
Titus Creek *Blackberry Lane to Mill Creek by Community College*	35	25
All Other Creeks *Within City Limits/UGA*	35	Not listed
All Piped Stream Segments *Applies to all creeks*	0	Not applicable

2.3 IMPERVIOUS SURFACE AND DISCONNECTED BUFFERS

In addition to generalized buffer mapping and summary statistics, spatial analysis was conducted to characterize land cover patterns under both stream regulation scenarios. Because development-related impacts are a primary consideration, the extent of impervious surface area was quantified within each buffer scenario, along with the proportion of areas functionally disconnected by impervious cover.

To more accurately represent functionally disconnected buffers surrounding development areas, a buffer-and-dissolve polygon aggregation technique was also applied. This approach consolidates developed buffer areas in close proximity and more effectively represents areas of functional isolation that are not impervious. A visualization of this technique is shown in Figure 2. This city-wide analysis is for estimating purposes only and is intended to support review of riparian buffer regulations.

Figure 2. Visualization showing a sample area along Garrison Creek with impervious surface cover in black, and additional functionally disconnected buffers in blue.

2.4 ASSUMPTIONS AND LIMITATIONS

The following assumptions and limitations apply to the spatial analysis and should be considered when interpreting the results:

1. Stream buffers were generated from mapped stream centerlines rather than the ordinary high water mark because centerline data were the available spatial data source.
2. Shorelines of the State are excluded from this analysis because they are regulated under the City's Shoreline Master Program.
3. Streams of unknown jurisdictional status were included.
4. The impervious surface and functionally disconnected buffer analyses are considered reliable for broad-scale planning purposes but should not be used for site-level determinations.
5. The analysis is limited by the accuracy of the underlying datasets. Although dataset limitations may compound across analytical steps, the source data are considered generally reliable for broad-scale planning purposes.

3. Results

The City of Walla Walla contains 43.2 stream miles, of which 2.4 miles (5.7%) currently have a 50-foot buffer, 27.2 miles (63.0%) have a 35-foot buffer, and 13.5 miles (31.4%) are piped and not associated with a regulated buffer. Under the dryland RMZ scenario, all 29.7 miles (68.6%) of non-piped streams would be assigned a minimum 100-foot buffer.

Existing impervious surfaces account for approximately 12.4% of the current buffer area, with an additional 3.5% classified as functionally disconnected, for a combined total of 16%. The remaining 84.0% of the buffer area is vegetated, representing a range of conditions from intact riparian forest to managed landscapes such as open fields and maintained lawns.

The total buffer extent is projected to increase from 268.8 acres to 757.4 acres under the dryland RMZ scenario, representing approximately 2.1% and 5.8% of the total city area, respectively. Within the expanded buffer, impervious surfaces are estimated to comprise 24.4% of the total area, with an additional 6.0% identified as functionally disconnected (30.4% combined). Although newly incorporated buffer areas are associated with a higher proportion of impervious cover and functional disconnection, approximately 69.6% of the total buffer area would remain vegetated, providing important ecological functions for stream and riparian systems. See summary in Table 3 below.

Table 3. Summary of areal calculations for stream buffers, impervious surfaces, and functionally disconnected buffer area.

Category	Current Buffers (ac)	Dryland RMZs (ac)
Total Area	268.8	757.4
Impervious Surface	33.4 (12.4%)	184.9 (24.4%)
Total Area – Functionally Disconnected Buffers	42.9 (16.0%)	230.4 (30.4%)
% of vegetated buffer area[1]	84.0%	69.6%

1 Vegetated areas in this GIS analysis may include a range of conditions from relatively intact riparian corridors to managed landscapes (e.g. lawns, parks) and other open spaces.

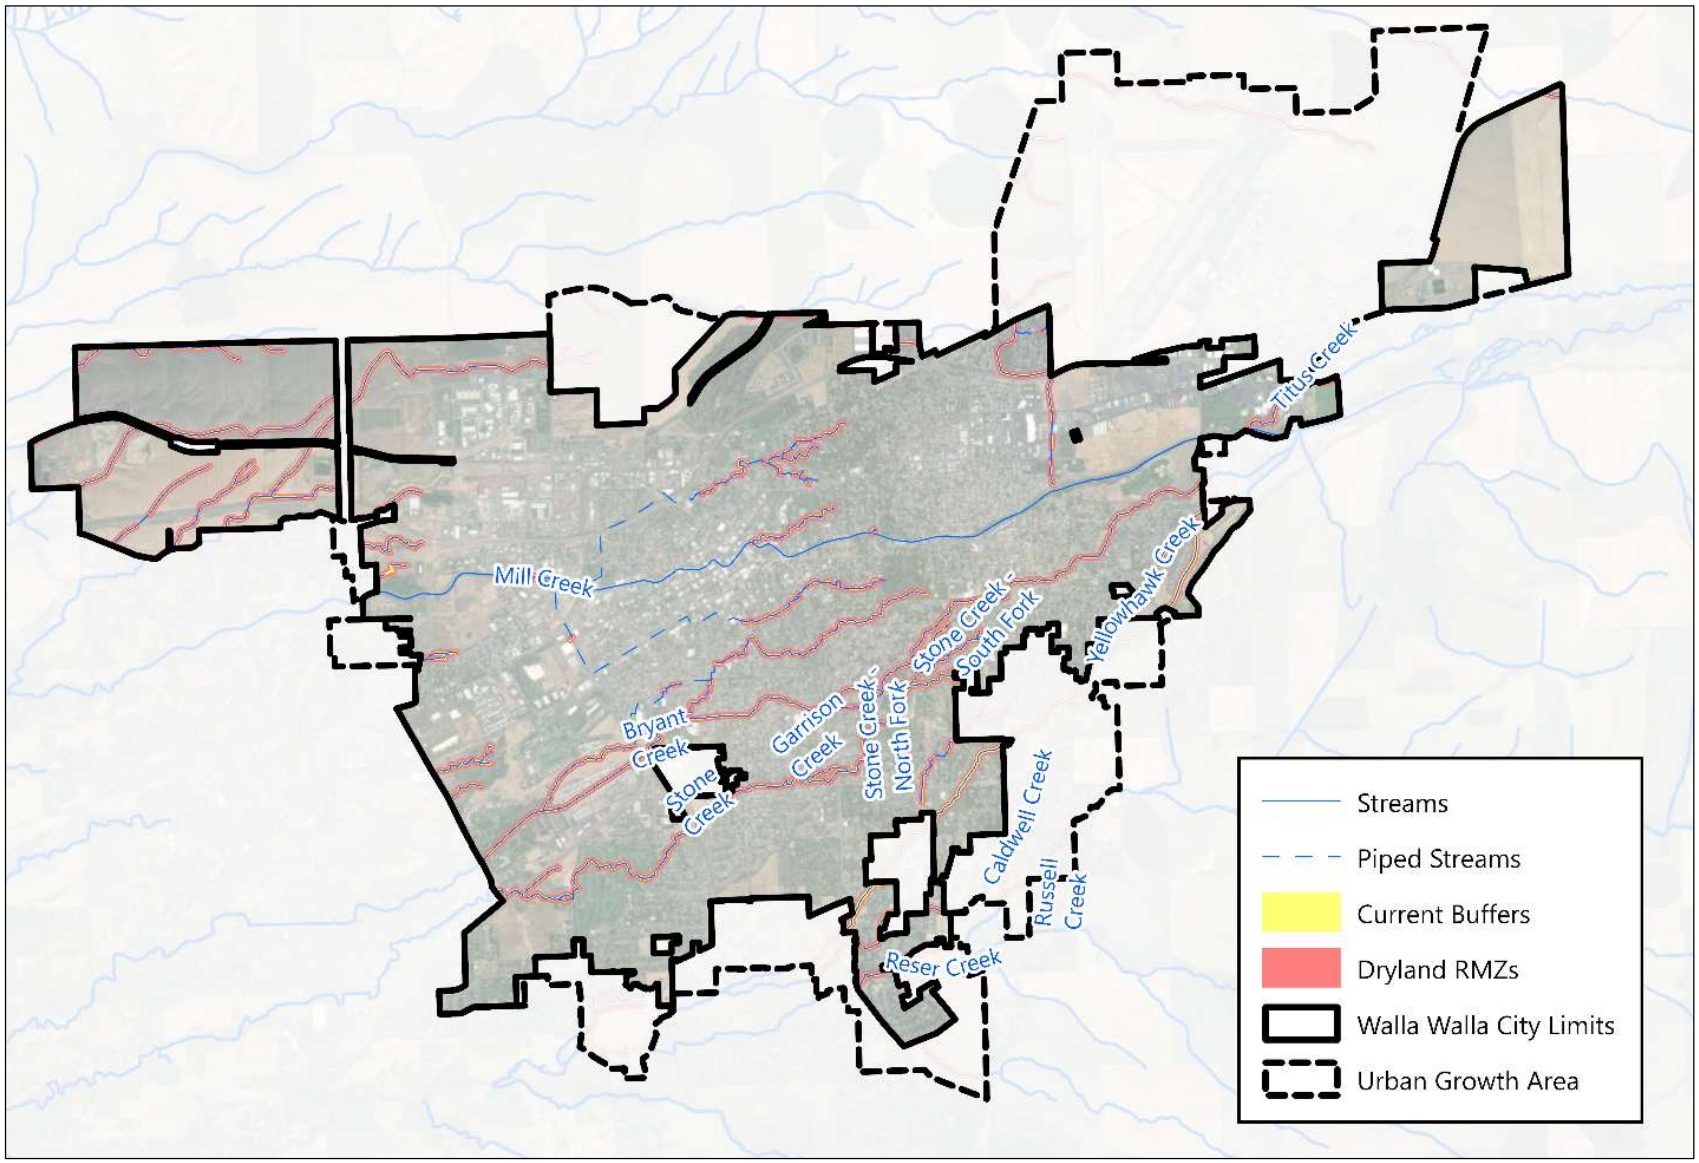

Figure 3. Current buffers and potential dryland RMZs in Walla Walla.

4. Discussion

This analysis indicates that applying WDFW's dryland RMZ recommendations would increase the total area subject to riparian protection within the City of Walla Walla. Under the current regulatory framework, most non-piped streams are regulated with 35-foot buffers, with a smaller proportion regulated with 50-foot buffers. In contrast, the dryland RMZ scenario applies a minimum 100-foot water quality buffer to all non-piped stream segments. This change would increase the total mapped buffer area from approximately 268.8 acres to approximately 757.4 acres, increasing the proportion of the city and UGA within mapped stream buffers from approximately 2.1% to 5.8%.

The impervious surface results also indicate that the dryland RMZ scenario would cover a greater proportion of developed or altered land than the current buffer scenario. Under existing buffers, impervious surfaces and functionally disconnected areas together account for approximately 16.0% of the mapped buffer area. Under the dryland RMZ scenario, the combined impervious and functionally disconnected area increases to approximately 30.4%. This pattern is expected in an urban setting because wider buffers extend farther into developed parcels, road corridors, and other land uses that may not currently provide riparian function.

Although the expanded RMZ scenario includes a higher proportion of impervious and functionally disconnected land, most of the land cover within potential riparian protection zones remains vegetated. Approximately 69.6% of the dryland RMZ is not impervious or functionally disconnected, and remains primarily vegetated. These vegetated areas may include a range of conditions, from relatively intact riparian corridors to managed landscapes such as lawns, parks, fields, and other open spaces. It may also include some areas of non-vegetated land that were not captured in the impervious surface data set, or landcover which is both non-impervious and non-vegetated. They may also include some non-vegetated areas not captured by the impervious surface dataset.

While vegetated areas vary in their ecological condition and functional value, they represent locations where existing riparian functions may be retained and where restoration, enhancement, or redevelopment requirements could improve long-term riparian function. For comparison, an estimated 84.0% of the area within current buffers is vegetated, whereas the newly added buffer area is estimated to be 62.6% vegetated.

The following WDFW riparian management recommendations should also be considered for implementation (Rentz et al. 2020):

- Maintaining and improving functions through regulatory and voluntary means,
- Increased regulations for clearing and grading activities within RMZs,
- Expanding Habitat Management requirements
- Implementing strict exemption requirements.
- Identifying and prioritizing restoration,
- Maintaining and improving riparian connections, and
- Applying stormwater management.

Additional strategies that the City of Walla Walla can consider to improve protection of riparian areas

are described in the WDFW Riparian Management Zone Checklist for Critical Areas Ordinances[1], which is a voluntary list of considerations in addition to the Commerce CAO Checklist. These strategies include:

1. **Restore or Enhance Riparian Vegetation:** For riparian/stream buffer areas to provide intended functions they are presumed to be densely vegetated with native vegetation typical of our ecoregion. Restoration actions recommended by WDFW include protecting existing habitat, connecting fragmented habitats, restoring natural processes, and creating or enhancing habitat. In some cases, buffer averaging may require enhancement measures to address degraded conditions.
2. **Improve Water Quality:** WDFW recommends a minimum 100-foot buffer width to provide for adequate pollutant removal to protect water quality as described earlier in this memo (Quinn, Wilhere, and Krueger 2020; Rentz et al. 2020). Water quality can also be supported by applying stormwater regulations and incentivizing low impact development and/or Salmon-Safe project certifications, where appropriate.
3. **Mapping Restoration Areas:** The City could consider mapping areas to pinpoint the best sites to restore considering connectivity and adjacency to other mapped Priority Habitats.
4. **Incentives to Daylight Streams:** To support restoration, the City may choose to provide regulations that specifically address daylighting streams at sites with existing legally established nonconforming uses. For stream daylighting or enhancement projects, this may include riparian vegetation improvements, increasing off-channel habitat, reversing channel incision, improving channel morphology, improving streambank stability, and increased quantity of large woody debris (Rentz et al. 2020).
5. **Reinforcing Mitigation Sequencing:** To reduce unnecessary habitat impacts within riparian ecosystems, it is recommended to provide improved regulations for mitigation sequencing. As described in WAC 365-196-380, "Avoidance is the most effective way to protect critical areas". Applicants should be required to demonstrate that mitigation sequencing was used in each project proposal that may impact habitat functions or values, including that avoidance was considered.
6. **Stricter Clearing and Grading Requirements:** It is recommended that the City limit clearing, filling, and grading activities within riparian areas, unless they are directly related to restoration, as these activities can negatively impact riparian ecosystems (Rentz et al. 2020). This includes considering restricting placement of on-site septic systems within 100' of riparian areas. It is also recommended that the City incorporate specific habitat assessment requirements as suggested in Riparian Ecosystems, Volume 2: Management Recommendations (Rentz et al. 2020).
7. **Expanded Habitat Management Plan (HMP) Requirements:** WDFW recommends that when an activity is proposed in a RMZ or could affect riparian or aquatic functions, a Habitat Management Plan (HMP) should be required. For consistency with the guidance in WDFW

[1] WDFW RMZ Checklist for Critical Areas Ordinances, August 2023: rmrcaochecklist.pdf

Riparian Ecosystems, Volume 2: Management Recommendations, the Habitat Management Plan requirements could be expanded to include the following: Measurable standards and expectations to monitor compliance and defined triggers for requiring more actions, i.e., performance standards. Examples of measurable standards could include extent of vegetative cover, composition of riparian vegetation and maximum invasive plant cover. The Habitat Management Plan is recommended to also identify the frequency of visits to monitor the site and specify who is responsible for preparing, reviewing, and submitting monitoring reports.

As the City of Walla Walla considers this assessment, we recognize stream regulations will be reviewed from an implementation feasibility perspective and are balanced with other Growth Management Act (GMA) requirements. Pursuant to WAC 365-195-915, when nonscientific information, including legal, social, cultural, economic, or political considerations, is used to support critical area policies or regulations that depart from recommendations based on the best available science, the record must: (1) identify the nonscientific information relied upon to justify the departure; (2) explain the rationale for deviating from science-based recommendations; and (3) identify any potential risks to climate resiliency and to the functions and values of the affected critical area(s), along with any additional measures adopted to mitigate such risks.

Acknowledgements

Many hours of painstaking work by dedicated experts went into the production of this document. The Core Team (listed in Appendix 1-A) persistently guided us through numerous challenges and did the bulk of the work by gathering and reading articles, dealing with problems with the database, and crafting and re-crafting the framework for the document. Katherine March, from state Fish and Wildlife (WDFW) also searched the public databases, generating long lists of articles to be considered for the synthesis, as well as provided valuable review. Kim Harper, while working as a staff member at Sheldon and Associates, accepted the difficult challenge of managing the database.

The authors and other members of the Core Team spent countless hours reading and summarizing articles and writing and re-writing text. Of special note is Tom Hruby whose knowledge of the literature and ability to translate scientific concepts into lay terms results in his valuable technical writing skills and contribution to many chapters.

Also of special note is the dedication and time spent by Dyanne Sheldon of Sheldon and Associates in the production of this document. She donated many hours of her own time toward the project, often burning the midnight oil to make sure articles were read and text written. Patricia Johnson deserves kudos for her work sifting through the voluminous information on compensatory mitigation and presenting it in a thorough yet easy to read manner.

Staff at the Washington Department of Fish and Wildlife provided review of internal drafts. Special thanks go to Steve Penland and Bob Ziegler for their valuable input and critique.

Sara Noland, 2N Publishing, is to be complimented for her excellent skills editing the draft document. Editing the draft was a real challenge given the numerous authors involved, each with a different writing style, and the changes that were initiated relatively late in the production process. We thank her sincerely for her patience and flexibility. Tom Noland, the other N in 2N Publishing, provided invaluable assistance in scanning and converting graphics into a format suitable for publication, as well as patiently trouble-shooting computer problems.

Thanks also to Mary Lynum for her role as Ecology support staff during completion of the review draft; Yolanda Holder and Paige Boule` from Ecology provided valuable assistance with finalizing and proofing the document. Keren Marzi of Sheldon and Associates is acknowledged for her effort designing several covers for the document, the final cover design being chosen by the Core Team. Thank you to Tim Schlender of Ecology for developing the web site and posting the draft and final versions of the document on the site.

Considerable acknowledgement is due to Dana L. Mock. The final production of Volume 1 would not have been possible without her diligence, hard work, attention to detail, and patience. Dana also took the lead on communications during the production of the final draft.

The document and this effort as a whole were the vision of Andy McMillan, who also obtained the funding from several sources. In addition, Andy wrote portions of the document and provided wise leadership and guidance, as well as contributing his unique ability to the resolution of complex problems.

Finally, of great importance is the acknowledgement of Teri Granger, the project manager. Teri coordinated every aspect of the project, facilitated meetings, provided encouragement to the authors and support staff, wrote and edited portions of the text, and provided overall management while working part time. Her oversight, management and attention to detail kept everyone on track and were greatly valued by all of her colleagues.

This document would never have been produced had it not been for the financial backing provided by the U.S. Environmental Protection Agency. The Washington State Departments of Ecology and Fish and Wildlife also contributed to the funding for this project. We thank the agencies for their support in undertaking such an ambitious endeavor.

Chapter 1
Introduction to the Document

This is the first volume of a two-volume series. This volume contains a summary and synthesis of the recent literature relevant to the science and management of wetlands in the state of Washington. Volume 1 describes what the scientific literature says directly about the topics described below. In some cases where scientific information is lacking, the authors present their own hypotheses or conclusions based on a process of deductive reasoning or their own observations. Hypotheses and conclusions based only on the authors' reasoning or observations are clearly labeled as such.

The focus of Volume 1 is freshwater wetlands in Washington. Estuarine and marine wetlands are discussed in this document only in regard to the wetland rating systems covered in the second volume.

The topics covered in Volume 1 are:

- How environmental factors control the functions of wetlands across the landscape and at individual sites, how freshwater wetlands are classified according to these controls, and what functions are performed by different classes of freshwater wetlands in the state
- How human activities and land uses affect the environmental factors that control the functions of freshwater wetlands
- How disturbances caused by human activities and land uses impact the performance of functions by freshwater wetlands
- How wetlands are protected and managed using common tools such as buffers and compensatory mitigation, including what the literature says about the relative effectiveness of these tools
- How cumulative impacts can result from current approaches to managing and regulating wetlands

Volume 2 of this series translates these scientific findings into guidance to local governments and others regarding programs they can or currently do use to protect and manage wetlands.

This work was collectively prepared by the Washington State Department of Ecology (Ecology), the Washington State Department of Fish and Wildlife (WDFW), and a private consulting firm. The U.S. Environmental Protection Agency (EPA) provided funding and assisted in its production. Representatives from these agencies, as well as staff from the private consulting firm, made up a team (the Core Team) that guided the project. See Appendix 1-A for a list of members of the Core Team.

Both volumes will be of use to all those interested in protecting and managing wetlands. The authors hope they will find these documents useful in gaining a greater understanding of the current science regarding wetlands in the state, their ecology and functions, as well as their protection and management. Examples of groups who might use these documents include federal, state, and tribal staff; planners; resource managers; wetland scientists; builders; farmers; environmentalists; and other concerned citizens.

Local governments, however, are the primary audience for this document. They are a key group involved in wetland protection in the state. Through the Growth Management Act (GMA) (Revised Code of Washington (RCW) 36.70A), every county and city in Washington must designate critical areas (including wetlands) within their boundaries and protect them. In 1995, an amendment to GMA (RCW 36.70A.172 [1]) required that all city and county governments must include best available science (BAS) when developing their critical areas policies and regulations.

This synthesis, therefore, may be of special interest to local governments that do not have the resources to complete their own review of the scientific literature. All local governments, however, should also consider locally and regionally specific information not included in this synthesis if it meets the criteria of a valid scientific process, as described below.

1.1 Best Available Science (BAS)

The Washington Administrative Code (WAC 365-195-905) provides assessment criteria to assist in determining whether information constitutes the best available science, i.e., by having been developed through a valid scientific process. A valid scientific process is one that produces reliable information that is useful in understanding the consequences of regulatory decisions and in developing policies and regulations that will be effective in protecting the functions and values of wetlands and other critical areas.

Appropriate sources of scientific information as defined in WAC 365-195-905 include:

- Research
- Monitoring
- Inventory
- Survey
- Modeling
- Assessment
- Synthesis
- Expert opinion

Information derived from any one of these sources can be considered scientific information if it possesses the required characteristics in WAC 365-195-905 (see Table 1B-1 in Appendix 1-B). For example, a synthesis such as Volume 1 is considered best available science when it has undergone peer review, describes the methods used to obtain the information, presents conclusions based on reasonable assumptions that are logically derived, places the information in proper context, and is well referenced. See Appendix 1-B for a list of all the characteristics of a valid scientific process and their definitions, as well as a table displaying the characteristics needed for each of the sources listed above to be considered BAS.

Methods for preparing and reviewing Volume 1

The primary steps taken to arrive at publication of this document include:

- Searching the literature
- Reviewing, sorting, and prioritizing the reference lists
- Obtaining the reference documents
- Reading and entering information from the documents in a database
- Writing and revising the text
- Obtaining peer and public review
- Responding to comments, revising the text, and completing the document

The processes used for these steps, including the scientific databases and the key words used to search them, are described in Appendix 1-C.

1.1.1 Volume 1 as BAS

Volume 1 meets the definition and characteristics required for a synthesis in the WAC. Findings from scientific journal articles, government publications, technical books, and other sources that meet the definition and characteristics of BAS in WAC 365-195-905 were used and referenced in the synthesis. Conference proceedings and personal communications were occasionally used when no other information was available. In some cases, we were unable to ascertain to what level these additional sources were peer reviewed.

In a few instances, we have cited data collected during the calibration of the *Methods for Assessing Wetland Functions* (Hruby et. al. 1999, 2000) (also known as the Washington State wetland function assessment methods or WFAM) and the Washington State wetland rating systems (Hruby 2004a, b). These data have not been published in scientific journals. However, these observations reported as "unpublished data" in Volume 1, were collected in the field by interdisciplinary teams of wetland experts and used to support and calibrate the function assessment methods and the wetland rating systems. The methods and rating systems have been extensively reviewed and field tested by peer experts as well as the public. The data themselves were offered for review on request during public review and continue to be available on request.

A peer review of documents concerning wetlands, specifically the function assessment methods, wetland rating systems, and these two volumes, means that comments were solicited from a broad range of people on a mailing list of hundreds. This included experts from various disciplines, not just a select few that were in house or close associates. All comments received were addressed. For these volumes, a response to each comment, including rationales for those not used to modify the drafts, has been prepared. To read the comments on Volume 1 and the authors responses go to http://www.ecy.wa.gov/biblio/0506007.html.

1.1.2 Making Hypotheses and Assumptions

As mentioned previously, in some places in the document we offer our conclusions based on the literature when the references searched do not provide specific information on a topic important for wetland management. In such instances, the authors clearly state that a hypothesis, assumption, or conclusion is being made. For example, we use statements such as "in the absence of research to the contrary, it can be assumed…," "it is possible to hypothesize…," or "it can be inferred that…"

In these cases, a description of the logic being used is provided which meets the criteria in WAC 365-195-905 for expert opinion, one of the sources of valid scientific information. The criteria include logical conclusions and reasonable inferences, context, and the use of references (see Appendix 1-B for definitions of these criteria). These hypotheses can be considered expert opinion according to WAC 365-195-905 in which expert opinion is defined as a "Statement of a qualified scientific expert based on his or her best professional judgment and experience in the pertinent scientific discipline. The opinion may or may not be based on site-specific information." To be considered best available science according to the WAC, an expert opinion must meet three of the six characteristics listed in the table in Appendix 1-B: logical conclusions and reasonable inferences, context, and references.

Logical conclusions and reasonable inferences are defined as "The conclusions presented are based on reasonable assumptions supported by other studies and consistent with the general theory underlying the assumptions. The conclusions are logically and reasonably derived from the assumptions and supported by the data presented. Any gaps in information and inconsistencies with other pertinent scientific information are adequately explained."

Context is defined as "The information is placed in proper context. The assumptions, analytical techniques, data, and conclusions are appropriately framed with respect to the prevailing body of pertinent scientific knowledge."

References are defined as "The assumptions, analytical techniques, and conclusions are well referenced with citations to relevant, credible literature and other pertinent existing information."

The statements that are hypotheses in this document meet these criteria because they are presented with a clear and logical train of thought and the conclusions are based on reasonable assumptions supported by other credible studies that are relevant. They are placed in context and referenced.

In addition, the definition of *synthesis* in Webster's 7th Collegiate Dictionary is "deductive reasoning" and "the combining of often diverse conceptions into a coherent whole." The statements that present hypotheses and assumptions are based on deductive reasoning.

There are a few instances in the document where the authors of Volume 1 offer their observations based on their own professional experience. These are usually limited to statements relating to protection measures used to manage wetlands. Such statements are clearly labeled as those of the authors only.

1.2 Scope of Volume 1

The focus of this document is freshwater wetlands of Washington State. We have included information on wetlands in other regions and countries and on aquatic systems in general when more local information is lacking and the data are applicable to the wetlands in Washington. See the following section (1.3) for more discussion on this topic. Volume 1 does not address streams or riparian areas that are not wetlands. We do, however, summarize some of the literature related to buffers on streams where the information can be transferred to wetlands.

Marine and estuarine systems are discussed only in regard to wetland rating systems and wetland types for which specific management is needed. Marine and estuarine wetlands were excluded primarily to keep the scope of the project in the range of the available funding. Some recent scientific information on coastal and estuarine wetlands has been summarized by WDFW, Ecology, and other agencies through the Aquatic Habitat Guidelines Project, which is available on the internet (www.wa.gov/wdfw/hab/ahg).

There are several types of freshwater wetlands that are highlighted in the wetland rating systems (described in Volume 2) that are not specifically reviewed in this synthesis (e.g., bogs, interdunal wetlands, and vernal pools). These wetlands are subsets of wetlands in the different hydrogeomorphic (HGM) classes described in Chapter 2. At the level of detail provided in this document, general information summarized about wetlands also applies to these types of wetlands in whatever HGM class and region of the state is appropriate.

The effects of growing cranberries in wetlands are also not covered in this volume because of the time and funding constraints of the project. The limited area of the state that is affected by cranberry production was also a factor. In addition, information related to the effects of silviculture and forest practices on forested wetlands is not included because this subject is being addressed in another document currently being developed (Cooke in press).

In addition, the synthesis in Volume 1 is limited to information that has a practical application to the management and protection of wetlands. For the most part, available documents from the past ten years were used as the primary sources for this synthesis. It was assumed that this most recent literature would incorporate relevant science from the preceding years. Older documents were used in instances where they had not been superseded by more recent studies.

This volume DOES NOT contain agency recommendations or suggestions for implementation of any program to protect or manage wetlands. Any recommendations provided in Volume 1 (for instance, in the section of Chapters 5 and 6 addressing buffers and compensatory mitigation) are those that have been described in the literature. They are included here only as part of the synthesis of existing scientific information. Agency recommendations are provided in Volume 2.

1.3 Relevance of Scientific Information to Conditions in Washington

One of the tasks in reviewing scientific information was to determine what is relevant to wetlands found in the state of Washington. Determining the relevance of scientific information encompasses two aspects. The first is the degree to which general conclusions and principles developed from existing information can be used to predict what will happen in new or different situations. The conclusions of a scientific study done at one time in one wetland with specific characteristics may not be directly transferable to circumstances that develop in the future or at sites that have different characteristics or situations.

The first aspect also encompasses the concept that science doesn't often provide a "bright line." In other words, science rarely supplies us with precise solutions for protecting and managing natural resources. Very few experiments demonstrate true cause-and-effect relationships. For example, in reviewing the literature for this volume, we found few studies that actually documented the effectiveness of different ways for managing the wetland resource (such as the effectiveness of buffers of a specific width at protecting a specific wetland function). Rather, most studies, for example, discuss the impacts of human activities on wetlands. As a result, guidance on protection and management based on scientific information (as presented in Volume 2) is, to a large degree, extrapolation and synthesis of all the information collected.

The second aspect is the relevance of information collected in one region to the conditions found in another region. We have relied, whenever possible, on literature that was derived in the Pacific Northwest. However, in some cases, scientific information generated in other regions of the United States, and to a lesser extent from other countries, was used. Authors of this volume judged whether each "out-of-region" reference was applicable to Washington by extrapolating, interpreting, and synthesizing the information to determine how it pertains specifically to Washington.

We understand establishing what is relevant to Washington is a subjective decision; however, two criteria were used in the decision. First, an "out-of-region" reference was incorporated in the synthesis if the basic ecological principles on which it was based are relevant to most landscapes. Second, it was incorporated if the geomorphic setting of the wetland in a scientific report was similar to those found in the Pacific Northwest and no information specific to the region (that meets the criteria of BAS) was found in our search of the literature.

One of the basic assumptions in ecological and biological research is that environmental processes operate in a similar way if the basic conditions are similar. For example, water is expected to flow downhill whether it occurs in Minnesota or in Washington. Denitrifying bacteria are assumed to transform nitrate to nitrogen gas wherever they are found as long as the soils are anaerobic. The particular wildlife species that are closely associated with wetlands may differ regionally, but frequently fill the same habitat niches in Ohio or California as they do in Washington. Thus, much of the information on functions developed outside the region is transferable to Washington. Regional differences in functions occur when the basic conditions differ, and we have tried to point this out where possible.

As mentioned previously, the definition of *synthesis* in Webster's 7th Collegiate Dictionary is "deductive reasoning" and "the combining of often diverse conceptions into a coherent whole." This is the goal we have set for Volume 1. Part of the role of a synthesis, thus, is to summarize many studies and scientific articles; glean the general principles that apply in most areas as well as those that relate specifically to the state of Washington; and try to determine if they will apply to future conditions based on best professional judgment of the authors and the reviewers of the document.

1.4 Overview of Volume 1

Volume 1 is organized into seven chapters. The chapters share a common organization, beginning with a reader's guide that describes the topics covered in the chapter and how the chapter is organized. An introduction then provides general background information, definitions, and clarifications. Each chapter describes the sources of information used and how well the subject is documented in the literature, particularly for the Pacific Northwest. The chapters also note gaps where information on an issue could not be found. Key points are summarized at the end of major sections and conclusions provided at the end of each chapter.

A brief summary of the contents of each chapter that follows and the appendices is provided below. In this document, page numbers are assigned to each chapter individually and are not sequential. The first number represents the chapter and the second the page number in that chapter (e.g., [3-2] represents page 2 in Chapter 3).

Chapter 2 – Wetlands in Washington and How They Function

Chapter 2 summarizes the information on how wetlands are categorized and how wetlands function in Washington State. It describes how functions are defined and introduces the concept that the performance of functions is controlled by a number of environmental factors within the wetland boundary (site scale) as well as in the broader landscape (landscape scale). The chapter then describes how some of the key factors that control functions are used to classify wetlands into groups that perform functions in similar ways.

The chapter goes on to describe functions of freshwater wetlands in Washington. Where applicable, the chapter discusses the differences in functions among wetland classes and in various areas of the state. The major functions described are those that were defined for the Washington State wetland function assessment methods (Hruby et al. 1999, 2000).

Chapter 3 – Environmental Disturbances Caused by Different Human Activities and Uses of the Land

In Chapter 3 the discussion shifts from wetland functions and the environmental factors that control the performance of functions to the major disturbances caused by human activities that affect wetlands and their functions. In this context, a *disturbance* is an event that changes an environmental factor that controls wetland functions. Ten disturbances (listed below) are discussed.

- Changing the physical structure within a wetland (e.g., filling, removing vegetation, tilling soils, compacting soils)
- Changing the amount and velocity of water in wetlands (increasing or decreasing the amount)
- Changing the fluctuation of water levels (frequency, duration, amplitude, direction of flow)
- Changing the amount of sediment (increasing or decreasing the amount)
- Increasing the amount of nutrients
- Increasing the amount of toxic contaminants
- Changing the acidity (acidification)
- Increasing the concentration of salt (salinization)
- Fragmentation (decreasing area of habitat and its spatial configuration)
- Other disturbances (noise, etc.)

The chapter continues with separate sections for four of the major types of human land uses in Washington State (agriculture, urbanization, forest practices, and mining) and the types of disturbances they cause. For each of these four land uses, the ten types of disturbances that change the factors controlling wetland functions (listed above) are discussed where applicable.

Chapter 4 – Negative Impacts of Human Disturbances on the Functions of Wetlands

Chapter 4 integrates the concepts discussed in Chapter 2 and Chapter 3. In Chapter 4, ten sections, one for each of the disturbances listed above, summarize how these disturbances ultimately leads to impacts on hydrologic functions, functions that improve water quality, and habitat functions.

Chapter 5 – The Effectiveness of Wetland Management Tools

Chapter 5 presents a synthesis of what the current literature reports on four tools currently used to protect and manage wetlands and their functions: the definition of wetlands, wetland delineation methods, wetland ratings, and regulatory buffers. In the section on definitions, the issues of biological versus regulated wetlands, small wetlands, isolated wetlands, and Prior Converted Croplands that are wetlands are discussed. This chapter does not provide language or recommendations for regulations or policy—those are provided in the second, separate volume containing guidance for protecting and managing wetlands in Washington (Volume 2).

Chapter 6 – The Effectiveness of Wetland Mitigation

Chapter 6 discusses another commonly used tool for managing and protecting wetlands, compensatory wetland mitigation. This topic is discussed in its own chapter because of the large volume of information available on this subject. Topics covered in this chapter include:

- Evaluation of the success of compensatory mitigation
- Compliance of mitigation projects with permit requirements
- Types of compensatory mitigation
- Replacement ratios and replacement of wetland acreage
- Functions provided by compensatory mitigation projects
- Reproducibility of particular types of wetlands (bogs, fens, vernal pools, alkali wetlands, and mature forested wetlands)
- Suggestions from the literature for improving compensatory mitigation

Chapter 7 - Cumulative Impacts on Wetlands

Chapter 7 discusses different types of cumulative impacts, and the loss of wetland area as the most easily assessed indicator of cumulative impacts. It goes on to present some of the causes of cumulative impacts in Washington. These include:

- Case-by-case permitting as a cause of cumulative impacts
- Lack of consistent plans and regulations between jurisdictions as a possible cause of cumulative impacts
- Implementation of regulatory programs at the local level as a possible cause of cumulative impacts

The chapter ends with a discussion in which the types of cumulative impacts are compared to the protection measures commonly taken by local governments.

Glossary

The glossary provides definitions for some of the technical terms used throughout Volume 1. Other terms are defined in the context of the sentence in which they appear and may not be included in the glossary.

References

The references cited in the text are listed separately at the end of Volume 1. Some of these references represent reviews or syntheses in which a researcher describes trends observed from numerous studies conducted in previous years. In these cases, we cite only the review document and not all the citations in the review.

Citations from the review by Adamus et al. (2001), however, are an exception. Portions of Adamus et al. (2001), a review of current scientific literature on the impacts of human activities on wetlands and their functions, were adapted and included in Chapter 4 with permission from Dr. Adamus. The list of cited references at the end of the document does include the literature sources from those portions of Adamus et al. (2001) that were adapted.

Appendices

The appendices of Volume 1 are as follows:

- Appendix 1-A identifies the team guiding the production of Volume 1 (the Core Team)
- Appendix 1-B describes the characteristics of a valid scientific process and types of scientific information defined by the Washington Administrative Code (WAC 365-195-905)
- Appendix 1-C details the methods used in the literature review and production of Volume 1
- Appendix 1-D lists the reviewers who commented on the draft of Volume 1
- Appendix 2-A provides information about various terms and methods that have been used to organize and group information about wetlands, such as classification, characterization, and rating
- Appendix 2-B lists the species of wildlife associated with wetlands in Washington and Oregon from Johnson and O'Neil (2001)

1.5 Public Involvement and Review of Volume 1

1.5.1 The Process of Public Involvement

The process for public involvement of Volume 1 included meetings of two focus groups, numerous mailings and extensive peer and public review. Ecology compiled a mailing list of scientists with wetlands expertise, local government planners, and other groups and individuals from various existing mailing lists used for other wetland-related projects.

In October 2001, Ecology sent out a focus sheet describing the project and a cover sheet that solicited the recipient's participation in the project. This sheet included a tear-off card that could be used to request that the sender be retained on the mailing list. The mailing list was then edited based on the returned cards.

Meetings of focus groups were held in January 2002 in Moses Lake and Olympia to begin the process of gathering input from the public on the project. These meetings were attended by various members of the Core Team, local planners, other staff from local government, and other interested parties. The purpose of these meetings was to help focus the project so that the synthesis would meet the needs of our primary audience, local governments. The meetings gave opportunities to the Core Team to present information on the project and to listen to questions and concerns from the attendees. Lists of keywords to use for the search of the literature were revised based on input from the focus groups.

In June 2002, Ecology sent out a mailer with an update on the project to the entire mailing list. It discussed the status of the project, timelines, and other issues.

In November 2002, Ecology staff contacted selected experts in various disciplines to solicit their review. The list of peer reviewers was not intended to be inclusive of all experts. The purpose was to make sure that each of the major topics in Volume 1 was reviewed by one or more recognized experts in that discipline. These expert reviewers were selected from academia, public agencies and private consultants.

In February 2003, Ecology sent another mailing to all those on the list to determine who wanted to comment on the draft of Volume 1. In June 2003, Ecology distributed a notice by email to update the public on revised target dates for distribution of the draft document for peer and public review.

The draft was distributed for general review in September 2003. Over 170 paper copies as well as CDs were sent to reviewers. An undetermined number of reviewers downloaded the draft from the project's web site. The experts asked to review the document were provided the draft at the same time as the general public. Instructions for providing comments and a questionnaire were also distributed with the draft document.

Several mailings were distributed since the fall of 2003 informing those listed about the status of revisions to Volume 1 as well as progress on the completion of the draft of Volume 2. The Core Team decided that a draft of Volume 2, containing guidance on

protecting and managing, should be completed before Volume 1 was completed. The draft of Volume 2 was distributed for comment in August 2004, during which time the authors began writing responses to comments and revising Volume 1. The review process for Volume 2 is described in Chapter 1 of that document.

1.5.2 Responding to Comments and Reviewing Suggested Literature

Twenty-nine reviewers provided comments on the draft of Volume 1. The reviewer's comments varied from cursory to very detailed, approximately 900 comments were submitted.

Initially, the Core Team organized and reviewed the comments and developed responses to the most substantive comments as individual or synthesized comments. The responses were posted on the project's web site in the spring of 2004. In addition, Ecology posted a list of all the comments that were submitted, organized by chapter, section and page. After the draft of Volume 2 was completed, each of the original comments was addressed by the authors. Each comment and a response to it have now been posted on the project's web site at the address below. Comments are organized by chapter, except for the beginning section that contains answers to questions in a questionnaire distributed to reviewers with the draft document.

As a part of the questionnaire, the reviewers were asked to provide any additional references they felt were pertinent to the subjects discussed. In addition, those who suggested changes or additions to the text were asked to provide citations. As a result, reviewers submitted several hundred new references. The authors reviewed this list and rated each as high, medium, or low importance using the same criteria used in the original search (see Appendix 1-C). Attempts were made to obtain and review all citations rated as high or medium. The results of this process, whether the reference was or was not obtained and why, are documented in a table at the end of the document containing the responses to comments.

Volume 1 and the responses to comments are available online

Ecology has developed a web site for this project on the Shorelands and Environmental Assistance Program web site. The web site includes a project description, contact information, current status of the project, and copies of the updates that were sent. The web site also includes a copy of the final version of Volume 1, as well as Volume 2, along with two documents containing the comments received and the authors' responses, one for each document. http://www.ecy.wa.gov/programs/sea/bas_wetlands/index.html

1.6 Conclusions

Volume 1 provides a summary of relevant scientific information related to wetlands in the Pacific Northwest and their management. The document should be useful to all those who have an interest in the protection and management of wetlands including agency staff, consultants, interested organizations, and citizens. It should be particularly helpful to local governments that are required under the Growth Management Act, to include best available science when developing and revising regulations protecting critical areas including wetlands. Volume 1 has been reviewed by technical experts (peer reviewed) and other interested parties. The intention of the project and the review process was to produce a synthesis of the current science on wetlands in the state of Washington that is easily understood, yet thorough and scientifically rigorous.

Chapter 2

Wetlands in Washington and How They Function

2.1 Reader's Guide to This Chapter

Chapter 2 presents information on wetlands in Washington and how they function. It introduces the ecological principles that help us understand the impacts of decisions we make about wetlands. It then expands on the newer ecological concept that the performance of functions is controlled by a number of environmental factors within the wetland boundary (site scale) as well as in the broader landscape (landscape scale). The chapter then describes these controls relative to regions and wetland types (classification of wetlands) in Washington before turning to detailed descriptions of the functions performed by the wetlands east and west of the Cascade Mountains and in different wetland classes.

To protect and manage wetlands, an understanding of wetland functions must be supplemented by knowledge of how these functions are affected by human activities. Chapter 3, therefore, goes on to describe how various land uses and activities disturb the environment, for example by causing excess nutrients, increased runoff and fluctuating water levels, and reduction in habitat. These disturbances in turn affect the environmental factors that control wetland functions. Chapter 3 describes what the literature says about the disturbances created by different land uses, while Chapter 4 goes into detail regarding how each disturbance affects particular wetland functions, including the organisms that use wetlands.

2.1.1 Chapter Contents

Major sections of this chapter and the topics they cover include:

Section 2.2, Basic Ecological Principles Useful in Managing Wetlands and in Understanding the Impacts of Human Activities describes five basic ecological principles that are useful in managing wetlands as identified by the Ecological Society of America. The principles include time, place, species, disturbance, and landscape.

Section 2.3, Introduction and Background on Wetland Functions describes the evolution of our understanding of wetland functions over the last few decades. It also defines the term *wetland functions.* The section describes how environmental processes at many geographic scales control the functions provided by wetlands. The section includes a diagram summarizing the environmental factors that control functions and how they interact with human disturbances. The difference between *functions* and *values* is also explained.

Section 2.4, Classification of Wetlands in Washington as a Key to Understanding their Functions begins by describing the common classification systems used to categorize wetlands. It discusses ecological regions (ecoregions) in Washington State and how wetlands across the

state are classified within the ecoregions into groups (classes and subclasses) that function in similar ways. The classes and subclasses of wetlands found in the state are described.

Section 2.5, Overview of Wetland Functions in Washington State introduces the functions of wetlands that are currently the focus of management efforts. These functions fall into three main categories: improving water quality, hydrologic functions, and providing habitat. Each category is described and the functions related to each are listed.

Section 2.6, How Wetlands Perform Functions in Washington State describes each of the wetland functions listed in Section 2.5. For each function, the text provides a general description of how the function is performed, and then goes into detail about how that function is performed by wetlands of various classes and in different areas of Washington.

Section 2.7, Chapter Summary and Conclusions summarizes the major concepts presented in the chapter.

2.1.2 Where to Find Summary Information and Conclusions

Each major section of this chapter concludes with a brief summary of the major points resulting from the literature review on that topic in a bullet list format. The reader is encouraged to remember that a review of the entire section preceding the summary is necessary for an in-depth understanding of the topic.

For summaries of the information presented in this chapter, see the following sections:

- Section 2.3.4
- Section 2.4.6
- Section 2.5.4
- Section 2.6.4

In addition, Section 2.7 provides a summary and conclusions about the overarching themes gleaned from the literature and presented in this chapter.

2.1.3 Sources and Gaps in Information

Our understanding of how wetlands function and the factors that control these functions has increased in the last two decades and much of this information has been published in the journal *Wetlands* (the journal of the Society of Wetland Scientists). Other journals that often carry papers on wetland functions include *Environmental Management*, *Restoration Ecology*, and the *Journal of the American Water Resources Association*.

Much of what we know about wetlands in Washington, their functions, and how functions are defined, is based on the collective expertise and judgment of teams of experts who developed the *Methods for Assessing Wetland Functions* (also known as the Washington State wetland function assessment methods of WFAM) (Hruby et al. 1999, Hruby et al. 2000) and who revised the

Washington State wetland rating systems (Hruby 2004a,b). These tools are methods that analyze the functions of wetlands in the state. This expert, regional information is critical because much of the knowledge in the scientific literature about wetland functions was developed outside the Pacific Northwest.

These tools can be considered a synthesis of the best available science for defining and understanding the functions performed by Washington's wetlands. The wetland scientists who developed these documents analyzed existing scientific information and extracted material that is relevant for Washington State. They also added their best professional experience, expertise, judgment, and field observations during development of these products. Existing scientific information is cited in these tools where it was judged relevant to Washington State.

The tools were developed using a formal process that was based on using consensus among wetland scientists in the region. The process included peer review and public comment. The documents resulting from the function assessment project and the rating system effort are cited in this synthesis as Hruby et al. (1999), Hruby et al. (2000), and Hruby (2004a,b). Information about these projects is also available at http://www.ecy.wa.gov/programs/sea/wetlan.html.

Major gaps in our knowledge of how wetlands in Washington function, however, still exist for the types of wetlands for which function assessment methods have not yet been developed. For example, there is little published information about the functions of "slope" wetlands and "flats" wetlands (see section 2.4.4 for a description of these wetland classes). There is also less published information on the wetlands in the arid region of the state.

2.2 Basic Ecological Principles Useful in Managing Wetlands and in Understanding the Impacts of Human Activities

Many decisions about the management and use of land are made with little attention to any of their ecological impacts. Thus, a better knowledge of the functioning of "ecosystems" is needed to broaden the scientific basis of decisions on using the land and managing it (Dale et al. 2000). In response to this need, the Ecological Society of America established a committee to examine the ways that land-use decisions are made and the ways that ecologists could help inform those decisions. The following discussion on the basic ecological principles that are useful in managing how we use the land (including wetlands) is derived from the report of the committee that was published in *Ecological Applications* (Dale, et al. 2000).

The committee identified five ecological principles that have implications for managing wetlands. The principles deal with time, place, species, disturbance, and landscape. Each is described briefly below and represents a summary of the information in Dale et al. (2000). (Note: the citations used by Dale et al. (2000) in developing these principles are not included in the summary.)

***Time Principle* - Ecological processes function at many time scales; some long, some short; and ecosystems change through time.** For example, activities in cells occur on the scale of microseconds to minutes, decomposition occurs over hours to decades, and soil formation occurs over decades and centuries. In addition, ecosystems can change from season to season, year to year, and decade to decade. Human activities that alter the species found in ecosystems or alter the biological, chemical, or geological cycles can change the pace or direction of these "natural" changes. Human activities have effects that can last decades or centuries.

***Species Principle* – Particular species and networks of interacting species have key, broad-scale effects on ecosystems**. Such "focal" species affect ecological systems in many ways. *Indicator species*, such as amphibians, help us understand the current condition of ecosystems. The status of indicator species helps us understand the status of larger groups of species, the status of key habitats, or as an indication of the action of some environmental stressor (disturbance). *Keystone species*, such as elephants, are those that have a greater effect on ecological processes than would be predicted from their abundance alone. *Ecological engineers*, such as beaver, alter habitat, and in doing so modify the survival and opportunities of many other species. *Umbrella species*, such as cougar, deer, or elk, either require large areas or use multiple habitats and thus overlap the habitat requirements of many other species. *Link species*, such as salmon, exert critical roles in the transfer of matter and energy across trophic levels or provide critical links in the transfer of energy in complex food webs.

***Place Principle* – Local climatic, hydrologic, edaphic (resulting from soils), and geomorphological factors as well as biotic interactions strongly affect ecological processes and the abundance and distribution of species at any one place**. Conditions in any one place reflect the variations that occur along gradients of elevation, longitude, latitude, and the many physical, chemical, and edaphic factors at a micro-scale. These factors provide the ecosystem with a particular appearance (e.g., a wetland formed in a glacial "kettlehole" is quite different from a wetland that formed in the "pothole" left behind in the basaltic surface of the Columbia Basin after the ice-age floods).

***Disturbance Principle* – The type, intensity, and duration of disturbances shape the characteristics of populations, communities, and ecosystems**. Disturbances are events that disrupt ecological systems. They may occur naturally (e.g., wildfires, storms, floods) or be caused by human actions (e.g., clearing land, building roads, altering stream channels). The effects of disturbances on ecological systems are controlled in large part by their intensity, duration, frequency, timing, and size and shape of area affected. Many ecosystems, such as Ponderosa pine forests, are maintained by a certain level and type of disturbance, such as fire. Changes in land use that alter the regime of natural disturbances or initiate new disturbances are likely to cause changes in species distributions, abundances, the composition of ecological communities and the functioning of the ecosystem.

***Landscape Principle* – The size, shape, and spatial relationships of land-cover types influence the dynamics of populations, communities, and ecosystems**. The spatial array of habitats and ecosystems make up the "landscape," and all ecological processes respond, at least in part, to this "landscape template." The kinds or organisms that exist and their interaction with ecosystem processes (e.g., decomposition, nutrient fluxes) are constrained by the sizes, shapes, and patterns of interspersion of habitat across a landscape. Human activities that decrease the size of habitat

patches or increase the distance between similar habitat patches can greatly reduce or eliminate populations of organisms.

These ecological principles underlie our understanding of how wetlands function and how they should be managed to protect their functions. They form the basis of the following discussion of how wetlands function, how human disturbances can impact those functions (Chapter 4), and how we should develop ways to protect and manage this resource (Volume 2).

2.3 Introduction and Background on Wetland Functions

2.3.1 An Evolving Understanding of Wetland Functions

The concept of wetland functions is relatively new in both the regulatory and scientific arenas. For many years wetlands were considered nuisances and wastelands (Washington State Department of Natural Resources 1998). The functions found within a wetland were not considered important enough to study and understand. Today, however, we know that the functions performed by wetlands are important and interacts with other aspects of the landscape around it. We have found that the structural components of a wetland and its surrounding landscape (such as plants, soils, rocks, water, and animals) interact with a variety of physical, chemical, and biological processes both within the wetland itself and the surrounding landscape. These interactions are called *functions*.

The concept of wetland functions has evolved since it was first introduced about four decades ago. Wetlands were first considered primarily to function as habitat for important species such as waterfowl. The factors that were thought to control how a wetland functions in this respect were the structural elements in a wetland. For example, how much open water did the wetland contain? What types of vegetation were found there? This interest in wetland structure led to the development of a classification system for wetlands in 1979 based on the vegetation and water regime (Cowardin et al. 1979). This system is still in use today. See Section 2.4.1 for more on this classification system.

It soon became apparent, however, that wetlands contribute more to the landscape than just habitat. During the 1980s much research was done on how wetlands filter pollutants and improve water quality. As a result, wetland engineers started to design and create wetlands specifically to treat wastewater (Hammer 1989). During the 80s wetlands were also recognized for their contribution to flood protection (Adamus et al. 1987).

The ongoing research in the 1980s also led to a realization that the functions performed within a wetland are controlled by a number of environmental factors both within and outside of the wetland. Climate was recognized as the major factor that affects how wetlands function at the largest geographic scale (Bailey 1995, Benda et al. 1998). Differences in temperature, rainfall, and seasonal and annual changes impact all aspects of interactions among organisms and their environment, including wetlands.

During the 1990's Brinson (1993b) and the National Academy of Sciences (National Research Council 1995) described and defined three other factors at a smaller geographic scale that can be considered primary controls of functions within a wetland:

- Geomorphic or topographic setting of the wetland
- Direct source of water to the wetland
- Hydrodynamics, or the direction of flow and strength of water movement within the wetland

More recently, however, scientists have become increasingly aware that functions performed by wetlands are also controlled by processes that occur at the scale of the watershed. There is currently an emphasis on trying to understand wetland functions in the context of how water, sediments, and nutrients move in a watershed (Bedford 1999). The surface geology and soils, the routing of water through the watershed, and the movement of sediments, large wood, nutrients, and other chemicals are all considered important factors in controlling how individual wetlands function (see Section 2.3.3).

2.3.2 How Wetland Functions Are Defined

The interactions that occur within a wetland occur at many scales as well, from the microscopic (such as bacterial decomposition of organic matter) to the continental (such as providing refuge and feeding for migrating waterfowl along the continental flyways). If every interaction that occurs within a wetland were identified as a separate function, the number of functions would be almost infinite. For example, the decomposition of organic matter by bacteria is a combination of many types of decomposition, one for each individual species of bacteria found in the wetland. Each bacterial species decomposes organic matter at a different rate and under different environmental conditions. Each of these could be considered a separate wetland function.

In contrast, a function can be a broad lumping of many environmental processes. For example, the "removal of imported elements and compounds" is a function identified in one method for assessing wetland functions (Brinson et al. 1995). At least a dozen nutrients and several hundred known contaminants can be found in surface waters. Therefore this function combines several hundred different processes of removal, one for each imported nutrient, contaminant, and other compound.

Wetland functions – The physical, biological, chemical, and geologic interactions among different components of the environment that occur within a wetland. There are many valuable functions that wetlands perform but these can be grouped into three categories – functions that improve water quality, functions that change the water regime in a watershed such as flood storage, and functions that provide habitat for plants and animals.

Furthermore, wetlands perform many types of functions, but not all wetlands perform the same functions, nor do similar wetlands provide the same functions to the same level of performance (Clairain 2002).

One of the initial tasks in defining functions, therefore, is to identify and group the processes and interactions that occur in wetlands into some manageable number of "functions." Most functions are generally grouped in terms of three broad categories (Adamus et al. 1991):

- Biogeochemical functions, which are related to trapping and transforming chemicals and include functions that improve water quality in the watershed
- Hydrologic functions, which are related to maintaining the water regime in a watershed and include such functions as reducing flooding
- Food web and habitat functions

Functions are subdivided into more specific groups by the environmental processes or interactions within the wetland that are related and are on a similar temporal and spatial scale. They are also grouped based on the needs for managing wetlands (Hruby 1999). For example, managers may need to know how well a wetland removes specific constituents that contribute to poor water quality such as sediment, nutrients, and toxic compounds, rather than having only a general assessment of the removal of elements and compounds that cause problems with water quality.

Table 2-1 gives examples of how the many different processes and interactions that occur in wetlands have been grouped under different names for various policy and regulatory purposes. They are organized into the three broad categories above (water quality improvement, hydrologic functions, and food webs and habitat).

The names of the categories to some degree reflect how broadly the function is defined. "The removal of all imported elements and compounds" is a broadly defined function, whereas "removing sediment" is a more narrowly defined function. Section 2.5 describes in more detail the functions that have been chosen for the Washington State wetland function assessment project and the Washington State wetland rating systems.

Table 2-1. Different ways of dividing wetland functions.

Wetland Evaluation Technique (WET) [a]	HGM Guidebook for Riverine Wetlands [b]	Mill Creek Special Area Management Plan (SAMP)[c]	Methods for Assessing Wetland Functions – Lowlands of Western WA[d]
Biogeochemical Functions Related to Improving Water Quality			
Nutrient Removal/ Transformation	Nutrient Cycling	Nutrient Uptake	Removing Nutrients
Sediment Stabilization	Removal of Imported Elements and Compounds	Sediment Stabilization	Removing Sediment
Sediment/Toxicant Retention	Retention of Particulates	Retention of Toxics	Removing Metals and Toxic Organic Compounds
Hydrologic Functions Related to Maintaining the Water Regime			
Floodflow Alteration	Dynamic Surface Water Storage	Floodflow Alteration	Reducing Peak Flows
Groundwater Recharge	Long-term Surface Water Storage	Groundwater Discharge	Decreasing Downstream Erosion
Groundwater Discharge	Energy Dissipation		Recharging Groundwater
	Subsurface Storage of Water		
	Moderation of Groundwater Flow or Discharge		
Functions Related to Maintaining Food Webs and Habitat			
Aquatic Diversity/ Abundance	Maintain Spatial Structure of Habitat	Habitat for Aquatic Species	General Habitat
Wildlife Diversity/ Abundance/ Migration Wintering	Maintain Interspersion and Connectivity	Habitat for Anadromous Fish	Habitat for Invertebrates
Production Export	Maintain Distribution and Abundance of Invertebrates	Habitat for Resident Fish	Habitat for Amphibians
	Maintain Distribution and Abundance of Vertebrates	Habitat for Migratory Birds	Habitat for Anadromous Fish
		Habitat for Resident Birds	Habitat for Resident Fish
		Habitat for Other Species	Habitat for Wetland-Associated Birds
			Habitat for Wetland-Associated Mammals

Relationship of functions to values

The scientific literature has in the past confused the terms wetland *functions* and wetland *values*. In fact, the term *functional values* was in common usage during the 1980s and early 1990s (e.g., Amman et al. 1986). The correct interpretation of the term *functional values* suggests that wetland values were functioning, which was not the intent of the phrase. As mentioned previously, wetland functions are the environmental processes that take place in a wetland. Society, however, does not necessarily attach the same value to all functions. Value is usually associated with goods and services that society recognizes, and not all environmental processes are recognized or valued. The National Research Council (1995) says the following about the differences between values and functions.

> *Because value is a societal perception, it often changes over time, even if wetland functions are constant. Value can change over time as economic development changes a region. The value of a wetland in maintaining water quality near a source of drinking water can be great even if the wetland is small (Kusler 1994). Some values can be mutually exclusive if they involve direct or indirect manipulation, exploitation, or management of wetlands. For example, production of fish for human consumption could conflict with the use of a wetland to improve water quality of water that contains toxins.*

There are three reasons for maintaining a clear distinction between functions and the services that wetlands provide (King et al. 2000). First, people can attach values to services, but usually cannot attach values to the underlying environmental functions and processes on which they depend. Second, the factors that affect the level of services a wetland provides are different from those that determine the levels of function. Third, different questions need to be addressed when considering values and functions. When assigning a relative value to a wetland, questions involving the importance and scarcity of the services need to be answered. Depending on the landscape context of the wetland, these may, or may not, be related to the levels of function in the wetland.

Generally, the important values of wetlands cannot be assessed or rated using the same methods as those used to assess functions (Hruby 1999). Analyzing values requires understanding a different set of factors than those used for functions (King et al. 2000).

2.3.3 Environmental Factors that Control Wetland Functions

"*Ecosystems are not defined so much by the objects they contain as by the processes that regulate them*" (Christiansen et al. 1989)

Functions of wetlands, as defined previously, represent interactions among the different components of the ecosystem and the landscape. Thus, functions can be influenced or controlled by changes to any one of these components. For example, a wetland may perform the function of providing overwintering habitat for coho, for which the presence of seasonal or permanent surface water is critical. This function will, therefore, change if the wetland is drained so no surface

water remains at any time. Changes in functions, however, can also be a result of alterations to the watershed outside the wetland boundary. For example, surface water in the wetland may also be eliminated if its water supply is diverted. Also if the gravel beds in which the coho spawn farther up in the watershed are disturbed, or if the flow in the stream is reduced to such an extent that the young can no longer swim to the wetland from the spawning areas, the wetland's support of coho overwintering habitat will be altered.

Likewise, the expression of one function in a wetland (such as habitat) can result in a change to the larger-scale environmental processes and the landscape. For example, if the conditions are right for beavers to settle in a wetland along a stream or river (i.e., the wetland functions as good habitat), the beavers will build a dam and create a ponded wetland. This will change the vegetation in the wetland and possibly alter other wetland functions such as improving water quality and storing flood waters. These changes may be important enough to change the water quality and the movement of water through that part of the watershed (a change in one of the primary controls of function).

Any factor that changes how well, or how much, a function is performed by a wetland can be considered a "control" of that function. Another term often used in the scientific literature is *driver*. The drivers of functions in wetlands determine how well the functions are performed. An action or occurrence that affects a control or driver is called a *disturbance* by ecologists (Dale et al. 2000). The type, intensity, and duration of disturbances can change the physical structure of the ecosystems and how they behave (ecosystem dynamics) (Dale et al. 2000).

Human activities create a disturbance that causes a "stress" on the ecosystem to which it responds. Scientists often use the term *stressor* to distinguish those disturbances that have a significant impact on an ecosystem from those that have little impact (see for example Adamus et al. 2001, Laursen et al. 2002).

In this document, however, we are not using the term *stressor*. All the disturbances discussed and reviewed here have documented negative impacts on wetlands and their functions. To avoid confusion, the term *disturbance* is used throughout this document.

Human uses of the land create a different set of disturbances than were present before human activities modified the land (Dale et al. 2000). The disturbances that are caused by human activities are discussed in Chapter 3, and the impacts these disturbances have on wetlands and their functions are described in Chapter 4.

The focus of research and management has been on functions and controls of functions that occur within the wetland itself and less on those that are a part of the landscape of the entire watershed. This has resulted from the fact that the need to define wetland functions has actually been driven by regulatory requirements and policy (Brinson et al. 1995, Clarain 2002). The policy has been to have a "no net loss of wetland area and function" at both the state and the national levels. However, this focus on functions confined to the wetland itself is changing. We are learning that managing wetlands requires an understanding of the "relationship of the individual wetlands to the landscape" (Bedford 1996) as well as the wetland itself.

A summary of the literature addressing the environmental factors that control wetland functions is presented below. First reviewed is the literature that addresses controls that occur at the scale of the wetland's contributing basin (that part of the landscape that contributes surface water to the wetland). The controls that are found within the boundary of the wetland (the site scale) are then described. The discussion includes a number of conceptual models that have been developed to help visualize and understand the complex interactions between wetland functions and environmental factors at different scales.

Terms used in this document to refer to environmental factors

Surface and subsurface water flows through the landscape within drainage systems. These drainage systems are often called basins, sub-basins, watersheds, or river basins depending on the size of the area. In this document, drainage systems are generally referred to using one of two terms:

- ***Watershed*** - A geographic area of land bounded by topographic high points in which water drains to a common destination.
- ***Contributing basin*** - The geographic area from which surface water drains to a particular wetland.

Environmental factors that affect wetland functions can occur at different geographic scales. In this document two scales are used.

- ***Landscape processes*** - Environmental factors that occur at larger geographic scales, such as basins, sub-basins, and watersheds. Processes are dynamic and usually represent the movement of a basic environmental characteristic, such as water, sediment, nutrients and chemicals, energy, or animals and plants. The interaction of landscape processes with the physical environment creates specific geographic locations where groundwater is recharged, flood waters are stored, stream water is oxygenated, pollutants are removed, and even wetlands are created.
- ***Site processes*** - Environmental factors that occur within the wetland itself or within its buffer. The interactions of site processes with landscape processes define how a wetland functions.

2.3.3.1 Environmental Controls of Functions at the Landscape Scale

Hydrogeologic Controls of Functions in Wetlands

Climate, geology, and the hydrologic characteristics in a watershed control how water, sediment, and nutrients move (Bedford 1999). Together, along with factors within the boundary of a wetland, these factors control the functions performed. Scientists call these large-scale, environmental factors the *hydrogeologic setting* of a wetland (Winter 1983, 1986, 1988, 1989, 1992, LaBaugh et al. 1987, Winter and Woo 1990). The following describes some models that have been developed to better understand these controls of wetland functions.

A hydrogeologic model created by Bedford (1996, 1999) concludes that wetlands develop and persist over time through the interaction of the hydrologic cycle with the landscape (Figure 2-1). This model views wetlands as part of an ecological system that is continuous with large-scale surface and groundwater systems. In this model, several geologic characteristics control the flow and chemistry of water, including the surface relief and slope of the land, the thickness and permeability of the soils, and the composition and hydraulic properties of the underlying geologic materials (Bedford 1999).

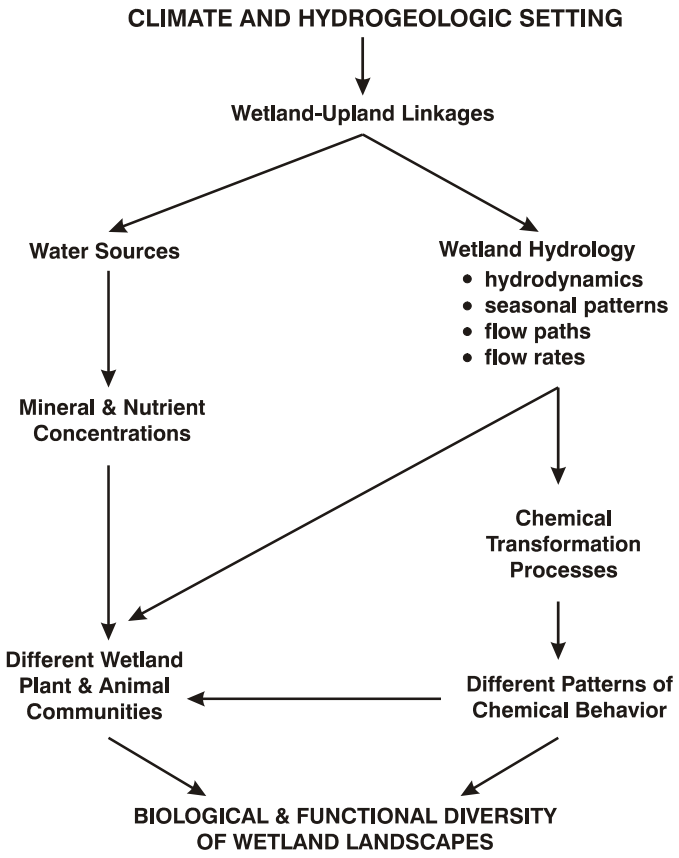

Figure 2-1. A model of the environmental factors that control wetland functions. (Bedford 1999; reprinted with permission)

In Bedford's hydrogeologic model, as in all the models discussed here, climate drives the large-scale water regime. Climate determines the precipitation and patterns of evapotranspiration that ultimately move surface and groundwater into and out of wetlands (see Figure 2-1). It also determines how sediments and chemicals (e.g., salts and nutrients) are eroded from bedrock and transported throughout the system.

A similar model to that of Bedford considers the contributing basin of a wetland in describing the factors that affect functions. This model, known as the "process-structure-function" model (Figure 2-2), was developed in conjunction with restoration plans for Northwest riverine systems. It is described in more detail in Beechie and Bolton (1999), Gersib (2001), and Stanley and Grigsby (2003). The model assumes that the biological, physical, and chemical characteristics (structure and functions) of aquatic systems including wetlands are determined by the interaction

of many processes operating at the larger scale of the landscape (Kaufman et al. 1997, Beechie and Bolton 1999). These processes include the movement of (Naiman et al. 1992):

- Water (surface and subsurface)
- Sediment
- Nutrients and other chemicals (salts, toxic contaminants)
- Large woody debris
- Energy (in the form of sunlight)

According to the "process-structure-function" model, the interactions of these processes with climate and geomorphology determine the structure within wetlands (e.g., substrate, plant communities). The wetland structure, in turn, is one factor that influences the type and performance of wetland functions.

For example, a wetland may produce large quantities of plant material and support the function of a rich food web. In order to provide this function, the wetland needs to have waters rich in nutrients coming into it, good exposure to sunlight, and a way for the production of plant material to leave the wetland into surrounding aquatic resources. The major controls for this function are the movement of water to and from the wetland, the movement of nutrients into and within the wetland, and an adequate source of energy.

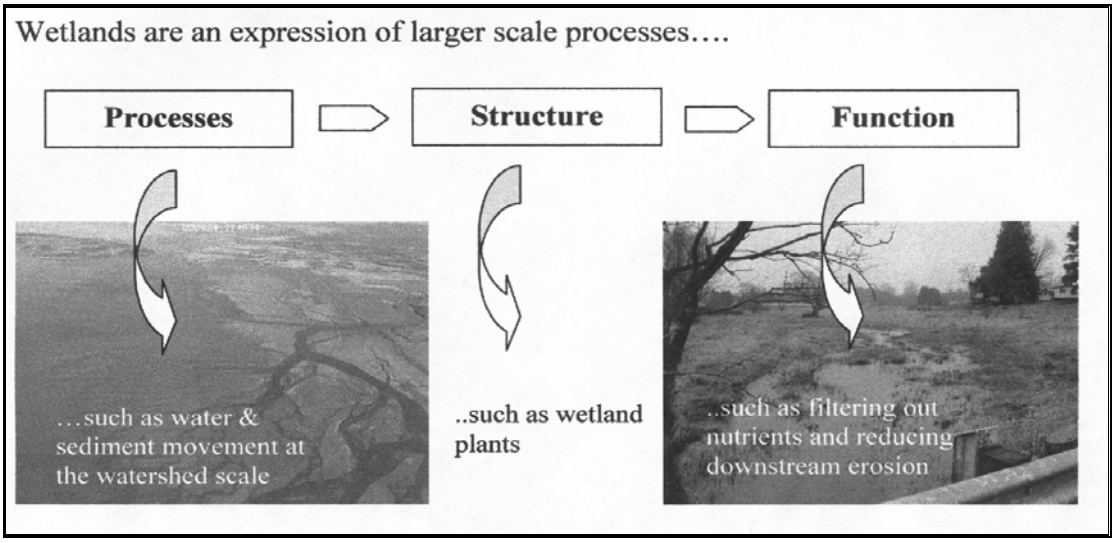

Figure 2-2. "Process-structure-function" model.

The "process-structure-function" model, like Bedford's, assumes that changes in land use affect processes such as the delivery of water, nutrients, sediment, and toxics to aquatic systems (Poiani et al. 1996, Mallin et al. 2000). These in turn affect structure and function within those aquatic systems.

Controls of the Habitat Provided by Wetlands

The abundance and richness of species within a wetland may be explained by the attributes of the surrounding landscape as well as by the characteristics found within the site itself (review in Dale et al. 2000). This is the landscape principle in ecology that was described in Section 2.2. The kinds of organisms that exist in a wetland and their interaction with landscape processes are constrained by the sizes, shapes, and patterns of interspersion of habitat across a landscape.

Understanding how animals and plants move between different habitats, and how the distribution of habitat "patches" affect the abundance of species, are the goals of a relatively new science called *landscape ecology*. The major result of recent research has been to highlight the fact that the distribution and abundance of species at an individual site, or "patch" is affected by the location, size, and shape of other patches of similar or different habitat in the surrounding landscape (Haila 2002, Manning et al. 2004). Some of the questions being asked in this research have been summarized by Bissonette and Storch (2002) and include:

- What is the relationship between species richness and the size of the patch of habitat?
- What is the relationship of species abundance to size of the patch of habitat?
- Are the interactions between different species modified as habitat is fragmented?
- Do the changes in the amount and quality of habitat along the edges of patches (edge habitat) change how an area functions as habitat?
- What are the relationships between relatively undisturbed corridors and the movement of species between habitat patches that have been separated by human activities?
- Do such connections increase species richness?

The research to date has highlighted the fact that there are no easy answers to these questions. The response of animals and plants to changes in patches, corridors, and distance between patches of the same habitat is very specific to the species involved (Haila 2002, Bissonette and Storch 2002, Haddad et al. 2003, Manning et al. 2004). For example, Haddad et al. (2003) studied ten different species living in the forests of South Carolina. Although the species were chosen because the authors thought they were likely to respond to the presence of corridors connecting patches of forest habitat, the abundance of only five of the ten species was positively correlated with presence of corridors. The abundance of the other five species was not correlated with the presence of corridors.

The study of patches and interaction between patches and species richness and abundance has taken on an increasing importance as human activities on the land have changed the distribution of habitats. The changes in habitat at the scale of the landscape caused by human activities are called *fragmentation*. The fragmentation of habitat consists of both reductions in the area of the original habitat and changes in the spatial configuration of what remains (Haila 2002). The results of current research on fragmentation have been difficult to interpret because much of it does not adequately separate the environmental factors that might cause differences in biodiversity (Haila 2002, Fahrig 2003, Manning et al. 2004). There is, however, one general conclusion that can be made from the current research. In reviewing over one hundred articles on

habitat fragmentation, Fahrig (2003) found that the loss of area available as habitat that results from human uses of the land has a large, consistently negative effect on the abundance and richness of species.

2.3.3.2 Environmental Controls of Functions at the Site Scale

The environmental factors at the large scale ultimately affect the environmental factors within the wetland itself (the site scale). As introduced earlier, Brinson (1993b) has developed a model that defines three factors that can be considered as primary controls of wetland functions at the site scale. Brinson's (1993b) model also uses characteristics of the landscape as factors that control functions in a wetland, but his model focuses primarily on the wetland itself relative to the two models discussed earlier (Bedford 1999). For example, Brinson's model emphasizes the shape and location of the wetland in the landscape and the type of water movement in the wetland that is dominant. The three factors defined by Brinson (1993b) are:

- The **geomorphic setting** (landscape position) of the wetland. Geomorphic setting is the topographic location of the wetland within the surrounding landscape and the geology that underlies it. In other words, is the wetland in a depression, on a slope, in a floodplain, or on the shores of a lake? The underlying geology also determines the soils present in the wetland, and this for example has an effect on the type and abundance of the plants found there.
- The **source of water** to the wetland. The sources of water can be simplified to precipitation, surface flow, shallow subsurface flow, and groundwater.
- The **hydrodynamics** of the wetland (the direction of flow and strength of water movement within the wetland). Hydrodynamics refers to the movement of water in the wetland and its capacity to do work. There are three qualitative categories of hydrodynamics: (1) vertical fluctuations of the water levels or water table, (2) unidirectional surface or near-surface flows that range from strong currents contained in channels to slow sheet flow down a slope, and (3) bidirectional flows resulting from tides or wind-driven currents in lakes.

In contrast, the "hydrogeologic" and "process-structure-function" models describe the surface and subsurface conditions across the landscape that control water processes within the wetland's contributing basin. The Brinson model (1993b) is the basis of the hydrogeomorphic (HGM) classification system which groups wetlands into similarly functioning groups. The classification system and an earlier classification, used for habitat mapping, are described in Section 2.4.1.

2.3.3.3 Summary of the Controls of Wetland Functions

To summarize the literature on the environmental factors that control functions, the authors of this synthesis have combined the terms and information used by several different authors to arrive at the list of factors in Table 2-2. These terms will be used in the following chapters because no standardized terms have been defined to describe all that happens at the different geographic, temporal, or spatial scales. In fact, the many articles that have been written on the subject of wetland functions and how they are controlled by environmental factors have engendered some

confusion in the terms used. For example, the term *process* has been used by different authors to describe a wide range of happenings that include the routing of water at a landscape scale as well as the chemical reactions by which bacteria change nitrate to nitrogen gas at the microscopic scale. Both of these factors are considered controls of functions.

The relationship between the environmental factors in Table 2-2 that control wetland functions and how they interact with human-caused disturbances is shown conceptually in Figure 2-3.

Table 2-2. Environmental factors that have been identified as controls of functions in wetlands. Most of the controls can occur at both the landscape scale and the site scale.

Environmental Factors that Control Functions in Wetlands	Scale at which the Control Occurs
Physical structure of wetlands (e.g., soils, vegetation, rocks)	Site
Biological structure of wetlands (e.g., physical structure of plants)	Site
Input of water (amount of water; maximum and minimum water levels)	Landscape and site
Fluctuations of water levels (frequency, amplitude, direction of flows)	Landscape and site
Input of sediment	Landscape and site
Input of nutrients	Landscape and site
Input of toxic contaminants	Landscape and site
Temperature	Landscape and site
Level of acid (pH)	Landscape and site
Concentration of salts	Mostly site
Size, connections, and distances of habitat patches in the surrounding landscape	Landscape
This table is a synthesis of the information presented by Winter (1983, 1986), LaBaugh et al. (1987), Winter and Woo (1990), Naiman et al. (1992), Brinson (1993a), Brinson et al. (1995), Bedford (1999), Beechie and Bolton (1999), Gersib (2001), Adamus et al. (2001), Stanley and Grigsby (2003).	

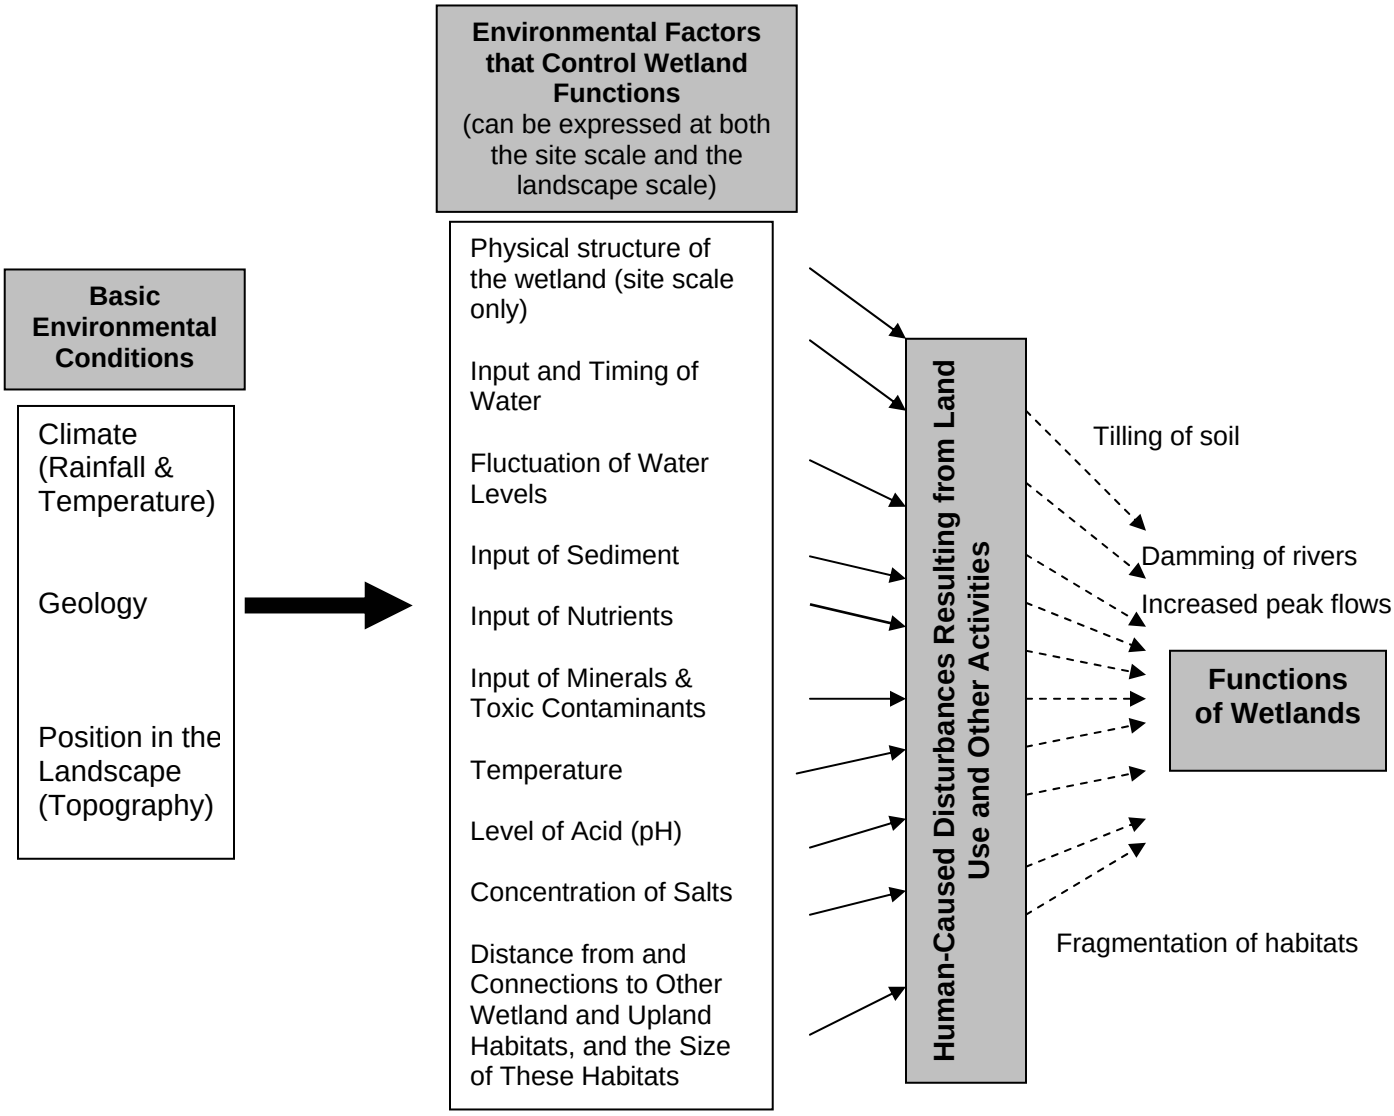

Figure 2-3. Diagram summarizing some major environmental factors that control functions of wetlands and how they interact with human-caused disturbances.

The basic environmental conditions establish and determine the factors that control the functions of wetlands. The controls can occur at both the landscape and site scales. Human activities cause disturbances that affect these controls in many different ways and thereby alter the performance of wetland functions. The figure gives some examples of the disturbances. This figure is a synthesis of the information presented by the same authors as listed in Table 2-2. The different models and information described above are the basis for Chapters 3 and 4 that describe the impacts of human activities on wetlands and their functions.

2.3.4 Summary of Key Points

- There are five basic ecological principles that are useful in managing wetlands. The principles deal with time, place, species, disturbance, and landscape.
- Wetland functions are the physical, biological, chemical, and geologic interactions among different components of the environment that occur within a wetland. There are many ways to define functions depending on specific needs for managing wetlands.
- Functions fall into three broad categories: biogeochemical, hydrologic, and maintenance of food webs and habitat.
- Society does not necessarily attach value, or equal value, to all functions.
- The functions that wetlands perform are controlled by environmental factors that occur in the broader landscape as well as within the wetland. The major controls of function are climate; geomorphology and soils; the source and quantity of water; the movement of water, nutrients, other chemicals, and sediments; energy in the form of sunlight; and biological interactions.
- The factors that control wetland functions interact with each other and there are many feedback loops. Environmental processes create the physical structure of the ecosystem and this in turn controls functions. Functions, in turn, can then modify the processes and structure as well.
- In order to gain a basic understanding of the ecological importance of functions provided by wetlands, they must be evaluated within the context of the landscape in which they exist.

2.4 Classification of Wetlands in Washington as a Key to Understanding Their Functions

This section presents a brief discussion of systems that scientists have developed to group or classify wetlands nationally and in Washington State in order to better assess how they function. It begins with an overview of two classification systems—the Cowardin classification, commonly used to inventory wetlands across the country, and the hydrogeomorphic or HGM classification, which is used to characterize how wetlands function. Understanding how wetlands are grouped and classified is a key to fully understanding how different types of wetlands in different areas provide different functions.

2.4.1 Commonly Used Classification Systems in Washington

2.4.1.1 The Cowardin Classification

The first commonly used classification system for wetlands was developed in 1979 by the U.S. Fish and Wildlife Service (Cowardin et al. 1979). The Cowardin classification system is hierarchical and includes several layers of detail for wetland classification that are based on:

- Water flow
- Substrate types
- Vegetation types
- Dominant plant species

The Cowardin classification system was developed to aid a national inventory of wetlands using aerial photographs (the U.S. Fish and Wildlife Service National Wetland Inventory or NWI). The wetlands in the state that can be identified from aerial photographs have been mapped using this classification system. The maps are available from the U.S. Fish and Wildlife Service in a digital form for GIS (http://www.nwi.fws.gov/). This information is a useful starting point for developing inventories of wetlands at the local level and looking at wetlands at the scale of watersheds and river basins.

> Methods for organizing our knowledge about wetlands have been called *classifications*, *categorizations*, *characterizations*, *ratings*, *assessments*, and *evaluations*. These groupings are meant to indicate the type of information a method provides. Unfortunately, the scientific community has been inconsistent in the use of these terms. Users of methods developed for analyzing wetlands should be aware of some of these problems with terminology. See Appendix 2-A for further discussion.

2.4.1.2 The Hydrogeomorphic Classification

Although the Cowardin classification is useful in developing wetland inventories from aerial photographs and incorporates some landscape factors, it was not designed to help understand how functions differ among wetlands. A more recent system of classification, called the *hydrogeomorphic (HGM) classification* (Brinson 1993b), was developed to specifically address differences in how various wetlands function. This classification method was chosen by the statewide wetland technical committee that guided the development of the Washington State wetland function assessment methods (Hruby et al. 1999).

As previously described in Section 2.3.3, the HGM classification is based on (Brinson 1993b):

- The position of the wetland in the landscape (geomorphic setting)
- The source of water for the wetland

- The flow and fluctuation of the water once in the wetland (hydrodynamics)

Classifying wetlands based on how they function narrows the focus of attention to a specific type of wetland. It also focuses on the functions that wetlands within that type are most likely to perform and the environmental factors that most likely control how wetlands of that type function.

The HGM classification also uses the concept of grouping wetlands by geographic units (domains and regions) in which some of the controls of functions that occur at the landscape scale are similar. The assumption is that many of the functions performed by wetlands are also similar.

The highest category in the HGM classification (called *class*) is defined nationally (Table 2-3) and is based on the geomorphic setting of the wetland (Brinson 1993b, Smith et al. 1995). Not all geographic units (domains and regions) contain all the wetland classes possible.

Within a region, wetland classes can be further divided by local experts into wetland subclasses and sub-subclasses (sometimes called *families* of wetlands) based on other geomorphic or hydrologic characteristics. The wetland experts in each region can, therefore, tailor the classification to address differences in the performance of functions by different wetland types in their region (Smith et al. 1995).

Geographic areas to which this classification system is applied in Washington and a description of the HGM classes in the state are described in Section 2.4.4.

Table 2-3. Characteristics of wetland classes in the hydrogeomorphic classification (from Brinson 1993a).

Hydrogeomorphic Class (Geomorphic Setting)	Dominant Source of Water	Dominant Hydrodynamics (Movement of Water)
Riverine	Overbank flow from a channel, or hyporheic (underground) flow in floodplain	One direction, horizontal
Depressional	Surface runoff, or the "daylighting" of groundwater	Vertical
Slope	"Daylighting" of groundwater on slopes	One direction, horizontal
Lacustrine (Lake) Fringe	Lake water	Two directions, horizontal
Flats	Precipitation	Vertical
Tidal Fringe	Overbank flow from estuary	Two directions, horizontal

2.4.1.3 Other Classifications Used in Washington

There have been several other classifications developed in Washington to group wetlands for the purpose of inventories and identifying different types of habitats. Kunze (1994) developed a classification of native, low elevation, freshwater wetlands in western Washington that is based on the dominant plant species found in the wetland. The purpose of this classification was to distinguish "natural heritage resources," whose identification was mandated by state law.

In eastern Washington, Kovalchik and Clausnitzer (2004) developed a classification of Aquatic, Riparian, and Wetland sites in the national forests that is also based on the dominant vegetation. The purpose of this classification was to describe the general geographic, topographic, edaphic (resulting from soils), functional, and floristic features of aquatic, riparian and wetland ecosystems. In addition, they developed it to describe successional trends in these ecosystems. Lastly it provides information on the values of the resources and opportunities for management (Kovalchik and Clausnitzer 2004).

2.4.2 Geographical Differences in Wetland Functions

Because hydrogeologic settings and the controls of functions vary across the landscape, it is important to identify the geographic areas in which these factors are similar. This allows the grouping of wetlands that function similarly.

For example, two conferences on wetland functions in the mid-1980s highlighted some of the differences between wetlands on the West Coast and those in the rest of the country (Horner 1986). Specifically, wetlands on the West Coast are different for the following reasons (Zedler 1985 as cited in Horner 1986):

- Drainage areas to West Coast wetlands are often smaller than those on the East Coast
- The coastal plain, with some exceptions, is not as large on the West Coast
- Soils in the West Coast region are often high in clay
- Conditions in a watershed are often highly erosive on the West Coast because of the steep topography
- Precipitation varies more seasonally on the West Coast than east of the Rocky Mountains

Even within Washington, the diverse areas of the state support many kinds of wetlands that vary in functions. For example, vernal pools on the scablands differ greatly from the floodplain marshes along the Snoqualmie River, and wetlands that formed in the potholes created by glaciers have different functions from those found along the shores of salt lakes in the Grand Coulee (Hruby et al. 2000).

Through the Washington State wetland function assessment project, there has been a major effort over the last eight years to build on previous work and to develop methods for assessing how wetlands function in different regions of the state. The methods are based on a formal process of quantifying the collective judgment of a group of local experts. This approach provides a

scientific basis for rapid methods in the absence of rigorous, site-specific scientific studies (Hruby 1999).

A statewide technical committee was formed in 1994 to guide the technical components of the function assessment project. In addition, several assessment teams, composed of experts in different disciplines, developed methods for specific wetland types and areas of the state (Hruby et al. 1999, 2000). At present, methods for four wetland types in the lowlands of western Washington and three types in the Columbia Basin of eastern Washington have been completed. These documents are available on the project's web site (http://www.ecy.wa.gov/programs/sea/wfap/index.html).

Another major effort has just been completed to incorporate differences among geographic areas and wetland functions into the Washington State wetland rating systems for eastern and western Washington. The Washington State Department of Ecology has been coordinating this effort, and teams of regional wetland experts and local government staff have provided technical expertise in writing the documents.

The geographic regions where wetlands function in different ways that have been identified by these teams of regional experts are described in the next section.

2.4.3 Wetland Regions in Washington

Wetlands in Washington are grouped first into "domains" and "regions" based on climate and other landscape features, then into "classes" by geomorphic setting, and finally into "subclasses" and "families" by the sources of water for the wetland and how that water moves (Hruby et. al. 1999, 2000, Hruby 2004a,b). These are some of the primary controls of wetland functions as described earlier. This section focuses on the wetland domains and regions. Section 2.4.4 describes the wetland classes and Section 2.4.5 the subclasses for Washington State.

The wetlands in Washington were divided into two ecological domains, East and West, when the Washington State wetland rating systems were first developed (Ecology 1991, 1993). The teams of wetland experts who revised the rating systems have kept this division (Hruby 2004a,b). At this highest level, the domains are based on the national classification of the environment (called *ecoregions*) developed by federal agencies (Bailey 1995). Wetlands on the west side of the Cascade Crest fall within the domain called *Humid Temperate* and those on the east side are in the *Dry* domain.

The term *ecoregion* was coined by J.M. Crowley (1967) and popularized by Robert J. Bailey (1976) to define a classification of ecosystems in the United States. Ecoregions are generally considered to be regions where climatic conditions are similar. As a result, the ecosystems there, including wetlands, are relatively homogeneous (Omernik and Gallant 1986). The concept was developed to help resource managers better understand regional differences in the environmental factors that maintain ecosystems and the relative importance of different factors that can change ecosystems (Omernik and Gallant 1986). The local maps of the ecoregions and their definitions are continually being updated by the U.S. Environmental Protection Agency laboratory in Corvallis, Oregon. The latest maps of ecoregions are available on the web at http://www.epa.gov/bioindicators/html/ecoregions.html.

The wetland experts working on assessments of function in the state further divided the domains into smaller regions because the two domains are too coarse a division for understanding how wetlands function in the state in a more detailed way (Hruby et al. 1999, 2000). At present there are five regions in the state (Figure 2-4) including three regions in the eastern domain and two in the western domain:

- Eastern domain:
  - Montane
  - Columbia Basin
  - Lowlands of Eastern Washington
- Western domain:
  - Montane
  - Lowlands of Western Washington

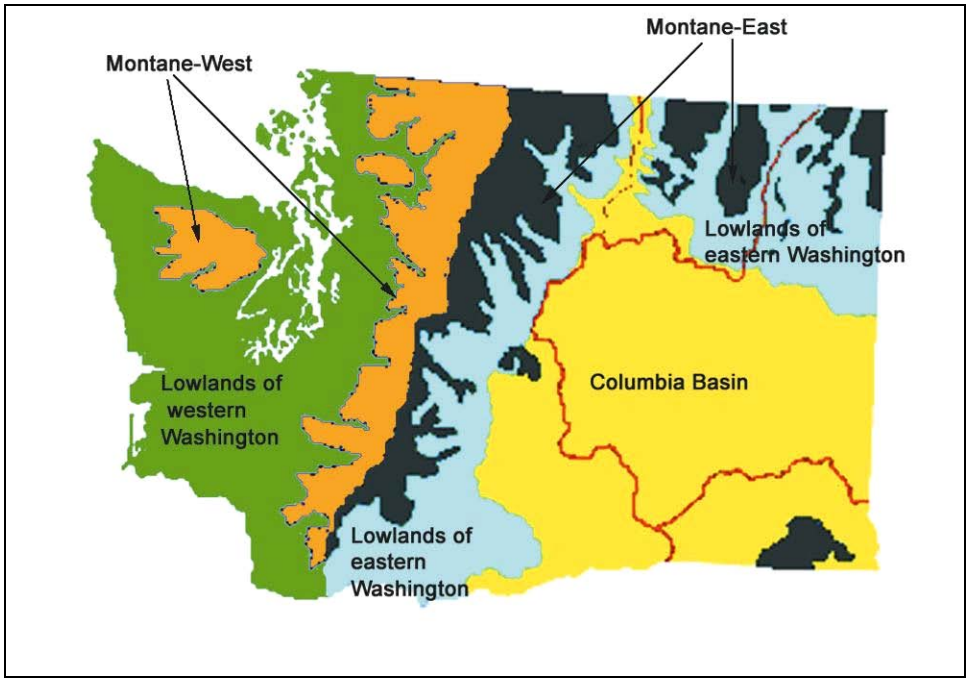

Figure 2-4. Regions in Washington used for classifying wetlands.

As mentioned previously, these regions of Washington are linked to the national classification of ecoregions developed by several federal agencies. The boundaries of the regions used in Washington, however, in some cases include parts of multiple ecoregions defined at the national level. The geographic extent of the Lowlands of Western Washington includes portions of three ecoregions within the Humid Temperate domain defined at the national level: the Coast Range, the Puget Lowlands, and the Willamette Valley (Hruby et al. 1999). Characteristics of these ecoregions are detailed in Omernik and Gallant (1986). The geographic extent of the Columbia Basin region, however, is the same as the Columbia Basin Ecoregion identified by Omernik and Gallant (1986).

At present, final definitions of regions have been developed only for the Lowlands of Western Washington and the Columbia Basin because these are the only two regions for which methods to assess wetland functions have been developed. The Montane regions (east and west of the Cascades) and the Lowlands of Eastern Washington have been defined with less detail because methods for assessing functions in these regions have not yet been developed. Generally the Montane regions include areas above 3,000 feet (915 m) elevation, and the Lowlands of Eastern Washington includes all other areas in the Dry domain, outside the Columbia Basin, and below 3,000 feet (915 m) elevation.

2.4.4 Description of the Wetland Classes for Washington

A brief description of wetlands in the different classes in Washington is given below. More detailed descriptions are available in Hruby et al. (1999, 2000).

2.4.4.1 Riverine Wetlands

The distinguishing characteristic of riverine wetlands in Washington is that they are frequently flooded by overbank flow from a stream or river (Hruby et al. 1999). Riverine wetlands are found in a valley or adjacent to a stream channel (Figure 2-5). They lie in the active floodplain of a river or stream and have important links to the water dynamics of the river or stream. The flooding waters are a major environmental factor that structures the environment in these wetlands and controls wetland functions. Riverine wetlands in some regions of Washington are defined by the frequency of overbank flooding (Hruby 2004a,b).

Figure 2-5. Riverine wetlands. Located in active floodplains where overbank flooding of the river or stream structures the wetland environment and controls its functions.

2.4.4.2 Depressional Wetlands

Depressional wetlands occur in topographic depressions that have closed contours on three sides (Figure 2-6). Elevations within the wetland are lower than in the surrounding landscape. The shapes of depressional wetlands vary, but in all cases the movement of surface water and shallow subsurface water is toward the lowest point in the depression. The depression may have an outlet, but the lowest point in the wetland is somewhere within the boundary, not at the outlet (Hruby et al. 1999).

Figure 2-6. Depressional wetlands. Located in topographic low areas that are closed on at least three sides (they may or may not have an outlet).

2.4.4.3 Slope Wetlands

Slope wetlands (Figure 2-7) occur on hill or valley slopes where groundwater surfaces and begins running along or immediately below the soil surface. They are usually found where the topography and local geologic conditions forces groundwater to the surface creating a zone of perennial or near-perennial moisture (Stein et al. 2004). Water in these wetlands flows only in one direction (down the slope) and the gradient is steep enough that the water is not impounded. The "downhill" side of the wetland is always the point of lowest elevation in the wetland (Hruby et al. 2000).

Figure 2-7. Slope wetlands. Located on slopes where groundwater daylights and runs at or just below the soil surface.

2.4.4.4 Lacustrine (Lake) Fringe Wetlands

Lacustrine fringe wetlands in Washington are found along the edges of deeper bodies of water such as lakes or reservoirs (Figure 2-8). These wetlands occur at the margin of topographic depressions in which surface water covers more than 20 acres (8 ha) and is deeper than 7 feet (2 m) in western Washington or 10 feet (3 m) in eastern Washington. The amount of open water and deep water also has to exceed 30% of the total area of wetland. The dominant surface water movement in lacustrine fringe wetlands has a horizontal component due to winds or currents, but there may also be a corresponding vertical component resulting from wind or seasonal water fluctuations (Hruby et al. 1999, 2000).

The definition of *lake fringe* is more specific than the definition of *lacustrine* used in the Cowardin classification described previously. The local teams of experts developing methods for assessing functions and the rating system decided to refine the definition of lacustrine to better reflect environmental conditions in the state.

Figure 2-8. Lacustrine fringe wetlands. Located along the edge of large bodies of water, such as lakes.

2.4.4.5 Flats Wetlands

Flats wetlands are rare in Washington. They occur in topographically flat areas that are hydrologically isolated from surrounding groundwater or surface water. The main source of water in these wetlands is precipitation. They receive virtually no groundwater discharge or surface runoff from areas outside the wetland boundary. This characteristic distinguishes them from depressional and slope wetlands (Hruby et al. 1999).

2.4.4.6 Tidal Fringe Wetlands

Tidal fringe wetlands occur along the coasts and in river mouths to the extent of tidal influence. The dominant source of water is from the ocean or a river that empties into the ocean; therefore these wetlands can be fresh or saline. The unifying characteristic of this class is the hydrodynamics. All tidal fringe wetlands have water flows dominated by tidal influences and water depths controlled by tidal cycles (Hruby et al. 1999). This document does not address tidal fringe wetlands.

2.4.5 Subclasses of Wetlands in Washington

Developing the HGM classification for Washington is an ongoing process, and not all subclasses for wetlands in the different regions have been defined. The wetland subclasses and families that have been defined in the four regions of Washington (as of February 2005) are listed in Table 2-4.

Although the HGM classification for wetlands in the state is not yet complete, the categories listed in Table 2-4 provide a useful tool to help separate wetlands into different types.

Table 2-4. Subclasses and families of wetlands in different regions of Washington State. (Hruby et al. 1999, 2000)

Class	Subclasses and Families by Region			
	Lowlands of Western WA	**Lowlands of Eastern WA**	**Columbia Basin**	**Montane (East and West)**
Riverine	• Impounding • Flow-through	ND	ND	ND
Depressional	• Outflow • Closed	ND	• Alkali • Freshwater • Long-duration • Short-duration	ND
Slope	ND	ND	ND	ND
Flats	ND	Probably does not occur in the region.	Probably does not occur in the region.	ND
Lacustrine (Lake) Fringe	ND	ND	ND	ND
Tidal Fringe	• Salt Water • Fresh Water	Does not occur in the region.	Does not occur in the region.	Does not occur in the region.
ND = Subclasses in the region have not yet been defined.				

2.4.6 Summary of Key Points

- The physical structure and functions of wetlands vary by region. The diverse regions of Washington support many kinds of wetlands that provide different functions. These differences are documented in the wetland function assessment methods and rating systems for Washington State.
- Wetlands in Washington are grouped first into domains and regions based on climate, then by geomorphic setting, and finally by the sources of water for the wetland and how that water moves. This is called the hydrogeomorphic (HGM) method for classifying wetlands.
- Hydrogeomorphic classes in Washington State include riverine, depressional, slope, lacustrine (lake) fringe, flats, and tidal fringe. Subclasses and families of wetlands are also defined by region (see Table 2-4).

2.5 Overview of Wetland Functions in Washington State

As described in the previous section, our current knowledge about wetland functions in different regions of Washington and among different HGM classes is based largely on the work of experts involved in developing the function assessment methods and ratings for wetlands in the state (Hruby et al. 1999, 2000, Hruby 2004a,b). Experts have developed methods to assess functions of riverine and depressional wetlands in several regions of the state. They have not discussed or identified the functions of freshwater wetlands in the flats, slope, tidal fringe, or lacustrine fringe classes, nor any functions of wetlands in the montane regions.

As mentioned in Section 2.3.2 there are many ways to group wetland functions. Functions that are currently defined for the state are listed on the following pages. The definitions are compiled from Hruby et al. (1999, 2000) and Hruby (2004a,b). Not all wetlands in a region, class, or subclass perform all of these functions. A more detailed description of each function is given in Section 2.6. As noted previously, functions are coarsely grouped into three main categories, those that improve water quality, those related to water regime in a watershed, and those that pertain to wildlife habitat.

> The functions selected for the Washington State wetland function assessment methods and the rating systems are narrowly defined to provide a level of specificity that is important to managing wetlands by decision-makers. The list of functions defined here does not represent all the functions performed by wetlands in the state. It does, however, represent the functions that were determined to be valuable by the experts that developed them and that need to be considered when managing wetlands (Hruby et al. 1999, 2000, Hruby 2004a, b).

2.5.1 Functions Related to Improving Water Quality

Removing Sediment: This function is defined in terms of the processes and characteristics that retain sediment within a wetland and prevent its downstream movement. A wetland performs this function if there is a net annual decrease of sediment load to downstream surface waters.

Removing Nutrients/Phosphorus: This function is defined in terms of the processes and characteristics within a wetland that remove phosphorus present in surface waters and prevent its movement into surface waters and groundwater.

Removing Nutrients/Nitrogen: This function is defined in terms of the processes and characteristics within a wetland that remove dissolved nitrogen present in surface waters or groundwater and prevent its further movement into surface waters or groundwater.

Removing Metals and Toxic Organic Compounds: This function is defined in terms of the processes and characteristics within a wetland that retain toxic metals and toxic organic compounds coming into the wetland and prevent their movement into surface waters and groundwater.

Removing Pathogens: This function can be defined in terms of the processes and characteristics within a wetland that retain or kill pathogenic organisms such as viruses and bacteria that can cause diseases in humans. This function was originally excluded from the water quality functions identified by the expert teams who developed the assessment methods and revised the rating system. They judged that the characteristics that determine this function are the same as those for removing sediment and removing toxic compounds. It has been added to the list of functions because reviewers of this document suggested it and it is a commonly recognized function (Kadlec and Knight 1996).

2.5.2 Functions Related to Maintaining the Water Regime in a Watershed (Hydrologic Functions)

Reducing Peak Flows: This function is defined in terms of the processes and characteristics within a wetland by which the peak flow in a watershed can be reduced during a major storm or snowmelt (i.e., events that would otherwise cause flooding).

Reducing Erosion: This function is defined in terms of the processes and characteristics within a wetland that detain high flows during storms and reduce the duration of erosive flows, thus decreasing downstream erosion in streams. This definition was developed for riverine and depressional wetlands. Wetlands along the shores of lakes (Jude and Pappas 1992) also protect resources from erosion but in a different way. For wetlands classed as lacustrine fringe, the function can be called "dissipation of erosive forces." This is defined as the processes by which wetlands reduce wave and current energies, thus reducing erosion of shorelines.

Recharging Groundwater: This function is defined in terms of the processes and characteristics within a wetland that allow surface water to infiltrate into the groundwater system.

2.5.3 Functions Related to Habitat

General Habitat: This function is defined in terms of the processes and characteristics within a wetland that indicate a general suitability and opportunity as habitat for a broad range of species. A suitable habitat for a suite of different fauna can be provided by a broad range of structures, vegetation, and interspersion of habitat types within the wetland and the upland habitats contiguous to a wetland. Characteristics in a wetland can be quite different and continue to provide highly suitable conditions for a range of species.

Habitat for Invertebrates: This function is defined in terms of the processes and characteristics within a wetland that help maintain a high number of invertebrate species.

Habitat for Amphibians: This function is defined in terms of the processes and characteristics within a wetland that contribute to the feeding, breeding, or refuge needs of amphibian species.

Habitat for Anadromous Fish: This function is defined in terms of the processes and characteristics within a wetland that contribute to the feeding, breeding, or refuge needs of anadromous fish species.

Habitat for Resident Fish: This function is defined in terms of the processes and characteristics within a wetland that contribute to the feeding, breeding, or refuge needs of resident native fish.

Habitat for Wetland-Associated Birds (called *Aquatic Birds* in the methods for eastern Washington): This function is defined in terms of the processes and characteristics within a wetland that provides habitats or life resources for species of wetland-associated birds. Wetland-associated bird species are those that depend on aspects of the wetland for some part of their life needs: food, shelter, breeding, or resting.

Habitat for Wetland-Associated Mammals (called *Aquatic Mammals* in the methods for eastern Washington): This function is defined in terms of the processes and characteristics within a wetland that support one or more life requirements of aquatic or semi-aquatic mammals.

Richness of Native Plants: This function is defined in terms of the degree to which the wetland provides a habitat for many different native plant species.

Supporting Food Webs (also called *Primary Production and Export* in the methods for western Washington): This function is defined in terms of the processes and characteristics within a wetland that support complex food webs within the wetland and surrounding resources through the export and assimilation of the primary productivity of the wetland. The function combines three major environmental processes: primary production, secondary production, and export of production.

2.5.4 Summary of Key Points

- Wetland functions are currently defined for Washington State in a relatively narrow manner to facilitate better wetland management and regulation by decision makers.
- Wetland functions defined in Washington fall into three general groups: functions related to improving water quality, functions related to the water regime in a watershed (hydrologic functions), and functions related to habitat.
- Not all wetlands in a region, class, or subclass perform all functions.

2.6 How Wetlands Perform Functions in Washington State

Table 2-5 summarizes the information on the functions that are, or are not, performed by the different freshwater wetland classes in Washington State. The following sections synthesize information available about each function and how the different wetland types in the state perform that function.

Table 2-5. Functions potentially performed by wetlands in different HGM classes in Washington. Data compiled from Hruby et al. (1999, 2000), Hruby (2004a, b).

Functions	Riverine	Depressional	Slope	Lacustrine Fringe	Flats
Improving Water Quality					
Removing Nutrients	P	P	P	P	P
Removing Sediment	P	P	P	P	NS
Removing Metals/Toxic Organic Compounds	P	P	P	P	P
Removing Pathogens	P	P	P	P	P
Hydrologic					
Reducing Peak Flows	P	P	N	N	NS
Decreasing Downstream Erosion/Dissipating Erosive Forces	P	P	P	P	NS
Recharging Groundwater	P	P	N	N	NS
Food Webs and Habitat					
General Habitat	P	P	P	P	P
Habitat for Invertebrates	P	P	P	P	P
Habitat for Amphibians	P	P	P	P	P
Habitat for Anadromous Fish	P	P	N	P	N
Habitat for Resident Fish	P	P	N	P	N
Habitat for Wetland-Associated Birds	P	P	NS	P	P
Habitat for Wetland-Associated Mammals	P	P	NS	P	P
Plant Richness	P	P	P	P	P
Support Food Webs	P	P	P	P	P

Key to symbols used in table:
P = Functions are performed
N = Functions are not performed
NS = (not significant) Functions are performed to a minor degree, but probably not at levels that are of importance to society.

2.6.1 Functions that Improve Water Quality

Wetlands greatly influence the quality of water in a watershed by removing many different types of contaminants. They help improve water quality, including that of drinking water, by intercepting surface runoff and removing or retaining inorganic nutrients, processing organic wastes, removing pathogens and reducing suspended sediments before they reach open water. The dominant processes for removing contaminants in wetlands are settling, chemical reactions in and with the soils, and biotransformations (reviewed in Hammer 1989, Moshiri 1993, Kadlec and Knight 1996).

Table 2-6 summarizes some of the major groups of contaminants that can enter wetlands and the primary mechanisms by which they are removed. The following sections discuss in more detail each of the major functions by which wetlands improve water quality.

Table 2-6. Primary mechanisms for removing contaminants in wetlands. Extracted from Hammer 1989, Moshiri 1993, Kadlec and Knight 1996.

Contaminant	Physical	Chemical	Biological
Sediment and other solids	Settling, Filtration		
Oxygen demand	Settling	Oxidation	Biodegradation
Hydrocarbons	Diffusion, Volatilization, Settling	Photochemical oxidation	Biodegradation, Evapotranspiration
Nitrogen compounds			Denitrification
Phosphorus compounds	Settling	Precipitation, Adsorption	
Metals	Settling	Precipitation, Adsorption, Ion Exchange,	Biotransformation
Pathogens	Residence time	UV radiation	Die-off, Other microbes

2.6.1.1 Removing Sediment

Sediment may enter wetlands in direct runoff from surrounding areas, as windblown dust, or in streams or rivers that flow through the wetland. Sediments deposited in wetlands are removed from surface flows, thereby improving water quality down-gradient. A wetland, however, will perform this function only if surface water contaminated with sediment actually enters the wetland.

Some general properties may be applied to all wetlands with respect to their ability to remove sediments (Phipps 1986). Within a given wetland, the deposition of sediment depends on several factors including (Phipps 1986, Johnston 1991, Fennessy et al. 1994, Gilliam 1994, Kadlec and Knight 1996):

- Residence time of the water that allows sediments to settle
- Wind and wave action that re-suspend sediments
- Size and amount of incoming sediment
- Vegetation

Generally, a high residence time for the water that allows settling and the filtration by vegetation are the major processes by which sediment is removed from surface water (Fennessy et al. 1994). Filtration is the physical adhesion and cohesion of sediment facilitated by vegetation (Adamus et al. 1991). The size of the particles that settle out is directly related to the increase in settling time achieved in the wetland (Adamus et al. 1991).

Typically a wetland with vegetation traps 80% to 90% of sediment from runoff entering the wetland (Johnston 1991, Gilliam 1994). Other studies have found that wetlands with open, deep, water may be as effective, or more effective, than vegetation in trapping sediments (Fennessy et al. 1994) because the residence time increased.

Wetlands can be more important for removing excessive amounts of sediments compared to other components of the landscape (Adamus et al. 1991). Another way to consider the importance of wetlands for removing sediments in a watershed is to analyze how much wetland area is needed to effectively remove sediments. Fennessy et al. (1994) report the following from their review of the literature:

- Watersheds in Wisconsin with only 5% of their area in wetlands trapped up to 70% of the sediment in the system
- In a North Carolina watershed, more than 20% of the total sediment deposition occurred in wetlands that represented only 11% of the area

The importance of any wetland for improving water quality depends, however, on the amount of sediment pollution in the watershed. Watersheds in which human activities loosen the topsoil (agriculture, development, and logging) are prone to have high sediment loadings. Wetlands in these watersheds are very important for maintaining water quality (National Research Council 1995).

Removal of Sediment by Wetlands of Various Classes and in Different Domains and Regions

The way wetlands remove sediment is not judged to be different in the two major domains of the state (the east side and the west side of the Cascades) (Hruby et al. 1999, 2000). However, the processes by which wetlands in Washington remove sediments differ somewhat among the different wetland classes as described below.

Wetlands in the Flats Class

Wetlands in the flats class, in general, do not remove sediment because by definition their major source of water is precipitation that falls within the wetland itself (Brinson 1993b). There is no opportunity for sediment-laden water to enter the wetland. All other types of wetlands perform this function to some degree because they receive surface water from outside their boundaries, and the surface water is never completely free of sediments.

Wetlands in the Depressional Class

Depressional wetlands that hold back all the surface water coming in (that is, those without a surface outlet) trap all the sediment they receive. Such wetlands are very effective at this aspect of water quality improvement wherever they are found in Washington (Hruby et al. 1999, 2000).

The removal of sediment in depressional wetlands with an outflow depends on how effectively they slow the water and allow settling, as well as the density of the vegetation that filters the incoming water. The same processes are present in depressional wetlands of both eastern and western Washington (Hruby et al. 1999, 2000).

Wetlands in the Lacustrine Fringe Class

Wetlands along the shores of lakes (lacustrine fringe) trap and retain suspended sediment by anchoring the shoreline, reducing resuspension of bottom mud by wind mixing, and slowing water velocities (Adamus et al. 1991). Even aquatic bed vegetation, which typically provides less resistance to water flow than emergent or woody plants, may reduce water movement enough to induce settling (Adamus et al. 1991).

Wetlands of this class have not yet been subjected to the thorough analysis required for developing a function assessment method. More definitive conclusions about Washington wetlands are, therefore, not available. However, no evidence has been reported that would negate the observations made in lacustrine wetlands in other parts of the U.S. that were reviewed by Adamus et al. (1991).

Wetlands in the Slope Class

Slope wetlands by definition (Brinson 1993b) do not impound surface water. The removal of sediment through settling is therefore not a factor in this class of wetlands.

Unpublished data collected during the calibration of the eastern Washington wetland rating system, however, suggest that slope wetlands may still play a role in removing sediment. For

example, slope wetlands in eastern Washington have vegetation that is usually thicker than the vegetation in the surrounding uplands (Figure 2-9). This vegetation acts like a filter to trap sediments coming from further upslope because it provides more resistance to the water flowing down the hillside (Hruby 2004a).

Figure 2-9. Slope wetland in the Columbia Basin that formed at a break in the slope. It has dense emergent plants that can trap sediment coming from the upslope areas.

Slope wetlands in western Washington have not yet been analyzed in terms of their potential to remove sediments, and it is not possible to report if similar processes and structure are found there. Models for assessing slope wetlands have, however, been developed for the Willamette Valley in Oregon. Two characteristics of slope wetlands identified there that contributed to the retention of sediments were the amount of ground covered by vegetation and the relative area of the wetland covered in hummocks (Adamus and Field 2001).

Wetlands in the Riverine Class

The removal of sediment in riverine wetlands is a somewhat different process. The vegetation and depressions within these wetlands trap sediment, but sediments are eroded by floods that recur every few years. The function of riverine wetlands is to stabilize sediment during the period between floods (Adamus et al. 1991). Wetlands are an integral part of the cycle of erosion and deposition in floodplains.

Phipps (1986) stated that the efficiency of sediment trapping by riverine wetlands in the Pacific Northwest has not been measured. This conclusion is still valid today, since no studies were found that quantified this function. The process of trapping sediments is still judged to be an important function on a watershed scale in Washington State (Hruby et al. 1999) and was

modeled during the development of function assessment methods. The characteristics of riverine wetlands that were judged important in removing sediments were as follows (Hruby et al. 1999):

- How much the stream or river meanders through the wetland
- How wide the wetland is relative to the width of the stream
- How much of the wetland is covered in vegetation that can act as a filter
- The amount of constriction in the outlet (if the wetland has an outlet)

2.6.1.2 Removing Phosphorus

Phosphorus can enter wetlands with suspended solids or as dissolved phosphorus. It is usually transported attached to particles rather than dissolved in the water (Raisin and Mitchell 1995). The major processes by which wetlands keep phosphorus from going farther downstream are (Mitsch and Gosselink 2000):

- The trapping of sediment on which phosphorus is adsorbed
- The removal of dissolved phosphorus by adsorption to soils that are high in clay content or organic matter
- Precipitation with calcium to form calcium phosphate

Wetlands that are effective at trapping sediments, therefore, are also effective at removing phosphorus. The discussion in Section 2.6.1.1 on the classes of wetlands that are effective at removing sediments also applies to removing phosphorus (Hruby et al. 1999).

The adsorption of phosphorus on soils is not permanent. Certain conditions during periods of extensive anoxia (lack of oxygen) may release phosphorus into the overlying waters (Adamus et al. 1991, Reddy and Gale 1994). In general, however, wetlands are a sink for phosphorus in watersheds (Adamus et al. 1991).

Other data also shows that phosphorus retention in wetlands is highly variable. Whigham et al. (1988) concluded that wetlands where waters had extensive contact with vegetation and/or organic litter were the most effective at phosphorus removal. Forested wetlands were only effective during flood events (when there was contact between waters and vegetation and more sediment deposition occurred). They found open water, lacustrine systems to be the least effective at phosphorus removal.

Johnston et al. (1997) observed that a wetland may remove phosphorus from incoming waters during one part of the year but at other times of year it may add phosphorus to water leaving the wetland. They hypothesized that the release of phosphorus from a wetland is due to the leaching of phosphorus from dying wetland vegetation.

The different pathways by which phosphorus can be trapped or released in wetlands are summarized in the quotation from a North Carolina State University web site in the box on the following page. Other sources that describe the many different ways phosphorus can be

adsorbed, de-sorbed, precipitated and bound to soils depending on pH, alkalinity and hardness of the water are Kadlec and Knight (1996), Richardson and Vepraska (2001) and Wetzel (2001).

Mechanisms of phosphorus removal

The following discussion from North Carolina State University summarizes the scientific literature on the ways in which wetlands remove and process phosphorus. (North Carolina State University undated).

Phosphorus removal from water in wetlands occurs through adsorption by aluminum and iron oxides and hydroxides; precipitation of aluminum, iron, and calcium phosphates; and burial of phosphorus adsorbed to sediments or organic matter (Walbridge 1993, Johnston 1991, Richardson 1985). Wetland soils can, however, reach a state of phosphorus saturation, after which phosphorus may be released from the system (Richardson 1985). Phosphorus export from wetlands is seasonal, occurring in late summer, early fall and winter as organic matter decomposes and phosphorus is released into surface water.

Dissolved phosphorus is processed by wetland soil microorganisms, plants, and geochemical mechanisms (Walbridge 1993). Microbial removal of phosphorus from wetland soil or water is rapid and highly efficient; however, following cell death, the phosphorus is released again. Similarly, for plants, litter decomposition causes a release of phosphorus. Burial of litter in peat can, however, provide long term removal of phosphorus. Harvesting of plant biomass is needed to maximize biotic phosphorus removal from the wetland system.

The potential for long-term storage of phosphorus through adsorption to wetland soil is greater than the maximum rates of phosphorus accumulation possible in plant biomass (Walbridge 1993, Johnston 1991). In alkaline wetlands, such as found in the West, phosphorus precipitates with calcium as calcium phosphate (Novotony and Olem 1994, Walbridge 1993). However, the presence of aluminum is the significant predictor of dissolved phosphorus sorption and removal from water in most wetland systems (Reddy and Gale 1994, Walbridge 1993, Richardson 1985). The capacity for phosphorus adsorption by a wetland, however, can be saturated in a few years if it has low amounts of aluminum and iron or calcium (Richardson 1985).

Wetlands along rivers have a high capacity for phosphorus adsorption because as clay is deposited in the floodplain, aluminum (Al) and iron (Fe) in the clay accumulate as well (Gambrell and Trace 1994). Thus floodplains tend to be important sites for phosphorus removal from the water column, beyond that removed as sediments are deposited (Walbridge 1993).

Removal of Phosphorous by Wetlands of Various Classes and in Different Domains and Regions

The way wetlands remove phosphorus is considered to be similar in the two domains of the state (the east and west sides of the Cascades). Firstly, wetlands that are effective at trapping sediments are also effective at removing phosphorus regardless of their location (Hruby et al. 1999, 2000). Wetlands of all types in both domains have the potential of trapping sediments and therefore removing any phosphorus adhered to it. This conclusion is based on data showing that most of the phosphorus entering a wetland is bound to sediment (Dortch 1996, Mitsch et al. 1995, Mitsch and Gosselink 2000).

Secondly, phosphorus entering a wetland in a dissolved form can also be retained because it binds to clay and organic soils (see box on the previous page). The HGM classification, however, does not separate wetland types by soil content (Brinson 1993b), so the presence of clay or organic soils is not specific to a particular wetland class or region. As a result it is not possible to differentiate this function between wetland types. In the absence of research to the contrary, it can be hypothesized that wetlands in all domains and regions of the state and in all wetland classes have the potential to remove phosphorus if they contain organic or clay soils that can bind phosphorus.

2.6.1.3 Removing Nitrogen

Wetlands in general act as sinks for nitrogen under both nutrient-enriched and un-enriched conditions (Adamus et al. 1991, Jansson et al. 1994). Nitrogen enters a wetland in the form of ammonium from animal wastes in runoff, as nitrate/nitrite from fertilizers in runoff and groundwater, or from air pollution (Adamus et al. 1991).

The efficiency of nitrogen removal is greater with longer retention times of the water, earlier plant community stages, and lower loading rates (Dorge 1984 as reported in Adamus et al. 1991). Wetlands are far more efficient at removing nitrogen from up-basin loading than either rivers or streams (Saunders and Kalff 2001), even though soluble nitrogen may be flushed out of wetlands at times of high flow (Johnston et al. 1990).

The major biochemical processes by which wetlands remove nitrogen are nitrification and denitrification. These respectively occur in alternating conditions where oxygen is present (aerobic) and oxygen is absent (anaerobic) (Johnston et al. 1990, Mitsch and Gosselink 2000, Vought et al. 1995, Saunders and Kalff 2001). Denitrification transforms the majority of nitrogen entering wetlands into nitrogen gas, causing between 70% and 90% to be removed from the aquatic system (Reilly 1991, Gilliam 1994).

In aerobic substrates, the bacteria *Nitrosomonas* can oxidize ammonium to nitrite. The bacteria *Nitrobacter* oxidizes nitrite to nitrate. This process is called nitrification (Mitsch and Gosselink 2000).

Nitrogen is completely removed from the aquatic system only by anaerobic bacteria that reduce nitrate to gaseous nitrogen during denitrification. The gaseous nitrogen volatilizes, and the nitrogen is eliminated as a water pollutant. Thus, the alternating reduced and oxidized conditions (anaerobic and aerobic respectively) of wetlands complete the nitrogen cycle and maximize

denitrification rates (Johnston 1991). First the aerobic bacteria change ammonium and organic nitrogen (decomposing plants and animals) to nitrate and nitrite, and then the anaerobic bacteria change the nitrate and nitrite to nitrogen gas.

Plants or microorganisms can use nitrate and ammonium for growth. Plant growth, however, does not really remove the nitrogen from the aquatic system because it becomes available again with the death of the plants or microorganisms that absorbed the nutrients (Adamus et al. 1991).

Nitrogen Removal by Wetlands of Various Classes and in Different Domains and Regions

The way wetlands are judged to remove nitrogen is similar east and west of the Cascades (Hruby et al. 1999, 2000, Hruby 2004a,b). Furthermore, the HGM classification does not separate wetland classes by the amount of oxygen in the soils (Brinson 1993b). The presence of alternating cycles of anaerobic and aerobic conditions is not specific to wetland types or regions. Therefore, it is not possible to differentiate this function between wetland types and regions.

Whether a specific wetland removes nitrogen or does not depends on the conditions found within the wetland, not on the type of wetland or its position in the landscape. The conditions that promote removal of nitrogen in wetlands of the state are seasonal inundation or saturation (Hruby et al. 1999, 2000). This indicates the soils alternate between aerobic conditions (when dry) and anaerobic conditions (when wet), and provides the optimal conditions for the gasification of nitrogen as described above.

2.6.1.4 Removing Metals and Toxic Organic Contaminants

The major physical, biological, and chemical processes by which wetlands reduce the amount of toxic materials moving into down-gradient waters are through sedimentation, adsorption, precipitation, oxidation, bio-degradation, and plant uptake (Adamus et al. 1991, Kadlec and Knight 1996, ITRC 2003).

- **Sedimentation** is a major process by which wetlands remove toxic compounds because some toxic compounds are bound to sediments or form insoluble compounds that settle out. For example, most heavy metals in urban runoff are adsorbed to sediment particles and are buried in sediment deposits within wetland soils (Newton 1989). Arsenic, Cadmium, Copper, Iron, Lead, Nickel, Silver, and Zinc are all metals that can be trapped through sedimentation (review in ITRC 2003). Thus, wetlands that are effective at removing sediments are also effective at trapping many toxic metals.

- **Adsorption** of the contaminants to the wetland soil is promoted by soils high in clay or organic matter (Adamus et al. 1991, Mitsch and Gosselink 2000). For example, wetlands can remove toxic metals from surface and groundwater if they contain clays, peat, aluminum, iron, and/or calcium (Gambrell and Trace 1994). Metals entering wetlands will bind to the negatively ionized surface of clay particles, or precipitate as inorganic compounds (metal oxides, hydroxides, and carbonates, depending on pH), or form a complex with humic materials (Gambrell and Trace 1994).

- **Chemical precipitation** is promoted by wetland areas that are inundated and remain aerobic, as well as those with pH values below 5 (Mengel and Kirkby 1982). Also, precipitation of dissolved iron is common in wetlands where anaerobic groundwater containing reduced iron compounds surfaces. In the aerobic surface environment the iron compounds oxidize into insoluble forms and precipitate out from solution. During this process metals and other compounds bind to the iron, and co-precipitate with the iron hydroxides (Kadlec and Knight 1996, Wetzel 2001).

- **Photochemical oxidation** is a pathway by which organic contaminants can be broken down into less toxic compounds through the action of sunlight (Kadlec and Knight 1996).

- **Biodegradation** is similar to oxidation, but in this case bacteria and other microbes break down organic contaminants. Degradation occurs under both aerobic and anaerobic conditions depending on the chemical structure of the contaminant (Kadlec and Knight 1996, ITRC 2003).

- **Plant uptake** of toxic compounds is maximized when there is significant wetland coverage by emergent plants (Kulzer 1990).

Removal of Toxic Contaminants by Wetlands of Various Classes and in Different Domains and Regions

Wetlands on the east and west sides of the Cascades were judged to function similarly in removing toxic contaminants (Hruby et al. 1999, 2000, Hruby 2004a,b). There may be some differences based on wetland class because some of the characteristics (such as effectiveness at trapping sediment) that are important for removing toxic compounds are dependent on the wetland class. Other differences do not depend on wetland class. In Washington, the experts who developed assessment methods judged that wetlands that remove sediments effectively are also effective at removing toxic compounds (Hruby et al. 1999, 2000).

The HGM classification, however, does not separate wetland types by the soils present or by how well they trap sediments (Brinson 1993b). The presence of clays, organic soils, aluminum, iron, or calcium in the soils is not specific to any wetland type. In the absence of research to the contrary, it can be assumed that wetlands in all regions of the state and in all wetland classes have the potential to remove toxic metals and organic compounds if they have the appropriate conditions that allow contaminants to sediment out, adsorb to soils, precipitate, biodegrade, or oxidize.

Wetlands with Clay Soils in Washington

As mentioned above, wetlands with clay soils can remove toxic contaminants because of the chemical properties of this type of soil. The term “clay” however, is applied both to materials having a particle size of less than 2 micrometers (25,400 micrometers = 1 inch) and to the family of minerals that has similar chemical compositions and common characteristics of crystal structure (Velde 1995). In Washington we find soils that are called “clays” that fit both aspects of the definition. In reviewing the descriptions of soils in the county soil surveys (e.g., Pringle 1990), there are three types of clay soils described in Washington.

- Those that consist of very finely ground rock formed by glaciers (called clays based on the size of the particles)
- Those that were deposited in lakes and the ocean (called clays either because of size or mineral composition)
- Those derived from the weathering of rocks in place (called clays based on mineral composition)

The scientific literature on the chemical properties of clays in relation to the adsorption of metals and organic pesticides, however, is based on the clays that are defined by their mineral composition and that are derived from weathered rocks such as bentonite, montmorillonite, and kaolinite (Fushiwaki and Urano 2001).

There is little information on the chemical properties of clays derived from glacial activity or aquatic sediments. County soil surveys (e.g., Debose and Klugland 1983) indicate that glaciers have played an important role in forming clays in western and northeastern Washington. Lacustrine (lake) and marine clays are also common in Whatcom County (Natural Resources Conservation Service 1992). These clays may contain chemically reactive minerals but it was not possible to confirm this assumption. Information from the soil survey of Whatcom County (Table J2 on the chemical properties of soils, released November 18, 2002), however, suggests that the clay soils of marine origin have a high cation exchange. This would indicate a high potential to bind metal and organic contaminants.

Wetlands with Volcanic Ash

Washington is relatively unique in the U.S. because it contains extensive areas where soils developed in volcanic ash (called Andisols). In addition, wetlands in the Columbia Basin often have a very fine layer of volcanic ash near the surface from the Mt. St. Helens eruption in 1980 (observations made by the technical team during the calibration of the methods for assessing wetland functions, Hruby et al. 2000).

In general, the cation exchange capacity of volcanically derived soils is high, due to a high surface area of the mineral and organic compounds (McSweeney 2004). Furthermore, volcanic ash that is washed or deposited into wet areas is in time transformed into bentonite clays (Bohor et al. 1976, Bohor et al. 1979). Thus, the ash found in wetland soils of Washington can be hypothesized to perform as clays to remove toxic compounds.

Wetlands with Organic Soils

Soils with a high content of organic matter have a high cation exchange capacity, and they are thus able to bind contaminants (Kadlec and Knight 1996). This is because the break down of plant material produces organic colloids that form complexes with contaminants (McSweeney 2004). Wetlands with organic soils such as peat bogs and fens in Washington State have the necessary soil conditions by definition (high content of organic matter) to react with and adsorb toxic contaminants.

Wetlands in the Depressional Class

A number of the characteristics that enhance the removal of toxic compounds are present more often in depressional wetlands, although all depressional wetlands do not have these characteristics. A higher number of depressional wetlands have slower moving water and finer sediments compared to riverine or slope wetlands (Brinson 1993b). Wetlands in which water moves slowly are better at removing toxics than those in which water moves rapidly. Slow moving water allows more time for chemical processes to occur before the water moves out of the wetland. This promotes the settling of fine sediments and the formation of organic soils (North Carolina State University 2002).

Depressional wetlands in the state more often have organic soils than wetlands in the other classes (observation is based on unpublished data collected by Ecology during the calibration of the Washington State wetland function assessment methods and the wetland rating systems 1998-2004). Depressional wetlands, therefore, can be assumed to usually have a higher potential to remove toxic compounds than wetlands in the other classes.

2.6.1.5 Removing Pathogens

Surface runoff coming into wetlands often contains large quantities of bacteria, particularly coliform bacteria and pathogens such as *Salmonella* (Hemond and Benoit 1988). Probably the most important mechanism for removing pathogenic bacteria from surface water is detention which is a function of residence time (reviews in Hammer 1989, Kadlec and Knight 1996).

Detention of the water in wetlands results in a natural die-off, and therefore removal from the water column, because many pathogenic bacteria cannot survive for long periods outside their host organism (Hemond and Benoit 1988). In addition, protozoa and other micro-organisms often found in wetlands actively feed on bacteria and can speed up the process of die-off (Hemond and Benoit 1988).

Removal of Pathogens by Wetlands of Various Classes and in Different Domains and Regions

The HGM classification does not separate wetland classes by their retention time or their populations of protozoa and other micro-organisms. Since these are the two major factors that account for the die-off of pathogens, it is not possible to differentiate how wetlands perform this function based on regional and hydrogeomorphic differences. Whether a specific wetland removes pathogens depends on the conditions found within the wetland, not on the type of wetland or its position in the landscape.

2.6.2 Functions Related to Maintaining the Water Regime in a Drainage Basin (Hydrologic Functions)

Wetlands play an important role in the water regime of watersheds (Mitch and Gosselink 2000, Bullock and Acreman 2003). Sipple (2002) provides a good summary of their role:

Because of their low topographic position relative to uplands (e.g., isolated depressions, floodplains), wetlands store and slowly release surface water, rain, snowmelt, groundwater and flood waters. Trees and other wetland vegetation also impede the movement of flood waters and distribute them more slowly over floodplains. This combined water storage and slowing action lowers flood heights and reduces erosion downstream and on adjacent lands. It also helps reduce floods and prevents water logging of agricultural lands. Wetlands within and downstream of urban areas are particularly valuable in this regard, counteracting the greatly increased rate and volume of surface-water runoff from pavement and buildings.

Because of their position on the landscape, wetlands at the margins of lakes, rivers, bays, and the ocean help protect shorelines and stream banks against erosion. Wetland plants hold the soil in place with their roots, absorb the energy of waves, and break up the flow of stream or river currents. The ability of wetlands to control erosion is so valuable that some states (e.g., Florida) are restoring wetlands in coastal areas to buffer the storm surges from hurricanes and tropical storms by dissipating wave energy before it impacts roads, houses, and other man-made structures.

The information available, however, indicates that the role of a wetland in the hydrologic cycle of a watershed is highly varied and depends on many factors. Bullock and Acreman (2003) reviewed 169 publications that report the results of scientific studies that quantified the hydrologic functions of wetlands. Their review confirms that wetlands exert a strong influence on the hydrologic cycle, but the actual functions performed by individual wetlands vary greatly. In many cases wetlands reduce floods and recharge groundwater while in other cases they may exacerbate floods or cause a net loss of groundwater (Bullock and Acreman 2003).

The following sections describe the characteristics of wetlands that reduce peak flow, reduce erosion, and recharge groundwater in Washington as determined by the teams of experts developing the methods for assessing functions and the rating system.

2.6.2.1 Reducing Peak Flows

Surface water that may otherwise cause flooding is stored to a greater degree in wetlands than typically occurs in terrestrial environments (Adamus et al. 1991). As a result, peak flows in streams and rivers are directly related to the total area of wetlands in the watershed, or to the area of wetlands in the headwaters of the system (National Research Council 1995). Wetlands reduce peak flows in streams and rivers by slowing and storing water in overbank areas and by holding back runoff that would otherwise flow directly downstream and cause more severe flooding (Reinelt and Horner 1995).

The function of reducing peak flows as defined in Washington State also includes the process of "floodflow desynchronization" (Hruby et al. 1999). This is a process that occurs at a larger, landscape scale. Desynchronization occurs when floodwaters are stored in many wetlands within the watershed. The release of water from these wetlands is staggered and gradual, resulting in more persistent flows but much lower peak flows (Adamus et al. 1991).

The characteristics of a wetland that indicate a potential to reduce peak flows include (Hruby et al. 1999, Mitsch and Gosselink 2000):

- The volume of water storage (depth of water stored multiplied by wetland area)
- The *live storage*, which is the storage above the bottom of the outlet
- Proximity of the wetland to flood waters
- Location of the wetland (e.g., along a river, lake, or stream)
- The amount of storage in the wetland relative to the volume of the flooding waters
- Lack of other upstream storage areas such as ponds, lakes, and reservoirs

Reduction in Peak Flows by Wetlands of Various Classes and in Different Domains and Regions

The importance of wetlands in reducing peak flows and how they perform this function differ in eastern and western Washington. This is a result of differences in the patterns of precipitation and snowmelt between the two areas (Hruby et al. 1999, 2000). The processes by which wetlands in Washington reduce peak flows also vary among wetland classes.

Wetlands of Western Washington

In **depressional wetlands of western Washington**, the characteristics within a wetland that reduce peak flows are the short-term storage capabilities of the wetland and the relative amount of flow captured from the upgradient contributing basin (Hruby et al. 1999). Short-term storage is often called *live storage* by hydrologists. It is the amount of water stored above the level of the outlet (if the wetland has one). Water stored below the outlet is called *dead storage* and was not considered to be important in reducing peak flows in western Washington (Hruby et al. 1999). The dead storage is usually filled by the time a flood event occurs and thus is not available to capture storm flows. Since most flooding events occur later in the fall, winter, and early spring, reductions in peak flow will occur only when a depressional wetland has some live-storage as well (Adamus et al. 1991, Hruby et al. 1999).

The expert teams who developed assessment methods for the state determined that the same assumption applies to the storage within the interstices of the soil (spaces between soil particles). Wetland soils in western Washington are usually saturated by the time most flood events occur, and storage in the soils was not judged to be important in reducing peak flows (Hruby et al. 1999) although it has been suggested as an important characteristic in other parts of the nation (Adamus et al. 1991).

Depressional wetlands with no outlet store all surface waters coming into them and therefore have the highest potential to reduce peak flows (Hruby et al. 1999).

In **riverine wetlands of western Washington**, the major characteristic judged to reduce peak flows is the storage provided by overbank areas (Hruby et al. 1999). As floodwaters rise, the waters overtop the banks of the river and fill the adjacent areas, many of which are riverine wetlands. The presence of a wide surface with an elevation at or near that of the river bank is the most important factor in reducing peak flows. As the flood waters overtop the banks they are

slowed down and the height of the flooding is reduced because the excess water is stored in these wetlands longer than the duration of the peak flows (Adamus et al. 1991, Hruby et al. 1999).

The **lacustrine fringe, flats, and slope classes of western Washington** have not been analyzed relative to reducing peak flows. The information available suggests wetlands in the flats and slope class do not play a major role in this function. Wetlands in the flats class by definition do not receive any runoff from surrounding areas (Brinson 1993b). Their effectiveness at reducing peak flows is to store only the precipitation that falls within their boundaries.

Wetlands in the slope class do not provide storage because by definition they do not impound any surface water (Brinson 1993b). Water flows to the lowest point on the slope and is then discharged. In fact, some studies show that slope wetlands may increase peak flows relative to surrounding uplands because their surface is saturated and rainfall in the wetland does not infiltrate (Bullock and Acreman 2003). The one role slope wetlands may play is to reduce the velocity of surface runoff by way of the thick vegetation often growing there (see Figure 2-9 for an illustration). The importance of vegetation on slopes in reducing flows has been well documented in studies of logging, though not specifically for slope wetlands (Lewis et al. 2001). It can be assumed that vegetation in slope wetlands plays the same role as vegetation in forested areas in reducing velocities of surface runoff (Hruby 2004a,b).

Wetlands of Eastern Washington

In **depressional wetlands of eastern Washington**, the characteristics within the wetland that reduce peak flows are the total storage capacity of the wetland and the relative amount of flow it captures from the upgradient contributing basin (Hruby et al. 2000).

The events that cause flooding in eastern Washington are different than in the western part of the state. Summer thunderstorms can cause flooding at times when most depressional wetlands are dry. As a result, the entire storage capacity of the wetland is available rather than just the live storage (Hruby et al. 2000). Depressional wetlands with no outlet store all surface waters coming into them and therefore have the greatest potential to reduce peak flows.

Riverine wetlands in eastern Washington are judged to function in a fashion similar to those on the west side (Hruby 2004a). Although function assessment methods have not been developed, the field work undertaken in calibrating the revised wetland rating system suggests that the major characteristic that reduces peak flows is also the storage provided by overbank areas (Hruby 2004a). See the previous discussion of riverine wetlands in western Washington for a more detailed description of storage by overbank areas.

Wetlands in **the lacustrine fringe and slope class** have not been analyzed in eastern Washington for their ability to reduce peak flows. The information collected during the calibration of the eastern Washington rating system, however, suggests wetlands in these two classes provide this function but not at the same levels as riverine or depressional wetlands (Hruby 2004a). Wetlands along the shores of lakes and reservoirs in eastern Washington tend to be small relative to the area of the lake (based on unpublished data, Hruby 2004a). They have some capacity to store water as the water levels in a lake rise, but the extra amount stored is often very small compared to the storage in the lake itself.

Furthermore, many lakes and reservoirs in this region have controlled and manipulated outlets. This means that the reduction in peak flows is directly controlled by humans and not by ecological processes. It is not possible, therefore, to assess how well these wetlands function to reduce peak flows based on their characteristics without an understanding of the protocols used to regulate the water levels in each reservoir.

By definition, wetlands in the slope class do not provide storage because any water flows to the lowest point and then is discharged (Brinson 1993b). However, their frequently dense vegetation reduces the velocity of surface runoff (see Figure 2-9) and thus can reduce the velocity of water somewhat. A wetland with dense vegetation will intercept more runoff and be more capable of reducing runoff velocity (and thus peak flows) than a wetland with less dense vegetation (Richardson and McCarthy 1994).

The importance of vegetation on slopes in reducing flows has been well documented in studies of logging (Lewis et al. 2001) though not specifically for slope wetlands. In eastern Washington the assumption is that vegetation in slope wetlands plays the same role as vegetation in forested areas in reducing peak flows (Hruby 2004a).

2.6.2.2 Reducing Erosion

The major process by which wetlands reduce downstream erosion is by slowing the velocity of water flowing downstream (Reinelt and Horner 1995, Adamus et al. 1991). The reduction in velocity depends on (Adamus et al. 1991):

- Channel constrictions that slow the flow of water
- Frictional resistance of the bottom
- Frictional resistance of vegetation

Jadhav and Buchberger (1995) state that the drag induced by plant stems increases with water velocity. This means that the relative reduction in velocity caused by plants increases as the speed of the water increases.

Reduction of Erosion by Wetlands of Various Classes and in Different Domains and Regions

The ways by which wetlands decrease erosion are somewhat different east and west of the Cascades. This is a result of the differences in the patterns of precipitation and snowmelt between the two areas (Hruby et al. 1999, 2000). The processes by which wetlands in Washington reduce erosion can also differ among wetland classes, as described below.

Wetlands of Western Washington

In **depressional wetlands of western Washington**, several characteristics were judged to influence a wetland's function in reducing water velocities (Hruby et al. 1999):

- Short-term storage capabilities of the wetland
- Characteristics of its outlet

- Amount of woody vegetation present
- Relative amount of flow captured from the upgradient contributing basin

Depressional wetlands with no outlet store all surface waters flowing into them. They have the greatest potential, therefore, to decrease erosion because no water leaves the wetland that could cause erosion (Hruby et al. 1999).

In **riverine wetlands of western Washington**, the major characteristic that reduces erosion is the amount of woody vegetation present that can provide a barrier to water flows (Hruby et al. 1999). As flood waters overtop the river banks, they are slowed down. The width of the wetland relative to the channel indicates how well the wetland can reduce velocity; the wider the wetland, the more water can spread out, becoming shallower and slowing down (Hruby et al. 1999).

Methods for assessing functions have not been developed for the **lacustrine fringe, flats, and slope classes in western Washington** and there is little information available on how these types of wetlands may perform this function. Wetlands in the flats class, however, are not expected to play a major role in this function. By definition, they do not receive any runoff from surrounding areas and therefore do not intercept waters that can cause erosion (Brinson 1993b).

Wetlands in the slope class, however, may decrease erosion to some degree because they often have thick vegetation relative to the surrounding uplands that reduces the velocity of surface runoff. Jadhav and Buchberger (1995) state that under dynamic conditions (high flows such as those found on slopes during storms) velocity is reduced by the drag induced by plant stems. Wetland detention time is therefore increased with vegetation density.

It can also be hypothesized that wetlands along the shores of lakes in western Washington (lacustrine fringe) may reduce erosion along the shore because of the vegetation they support. This would both anchor the shoreline and dissipate erosive forces (Adamus et al. 1991). Wetlands that have extensive, persistent (especially woody) vegetation provide protection from waves and currents associated with large storms and snowmelt that would otherwise penetrate deep into the shoreline (Adamus et al. 1991).

Wetlands of Eastern Washington

In **depressional wetlands of eastern Washington**, the characteristics within the wetland that decrease erosion are the total storage capacity of the wetland and the relative amount of flow captured from the upgradient contributing basin (Hruby et al. 2000). The events that cause erosion in eastern Washington are different than in the western part of the state. Summer thunderstorms can cause highly erosive flows at times when most depressional wetlands are dry (Hruby et al. 2000). As a result, the entire storage capacity of the wetland is usually available to reduce water velocities rather than just the live storage. Depressional wetlands with no outlet store all surface waters coming into them and therefore have the most potential to decrease erosive flows.

Riverine wetlands in eastern Washington function in a similar fashion to those on the west side (Hruby 2004a). Although experts have not developed function assessments, the field work

undertaken in calibrating the revised wetland rating system suggests that woody vegetation within the wetland is key in reducing erosive flows by slowing velocities during floods.

Function assessment methods for the **lacustrine fringe and slope classes** have also not been developed in eastern Washington. There is therefore no clear understanding of how they function to decrease erosion. It can be hypothesized, however, that wetlands of both classes can function to reduce erosion to some degree in a manner similar to these types of wetlands in western Washington (see discussion above).

2.6.2.3 Recharging Groundwater

The recharge of groundwater is the movement of surface water, usually downward, into the ground. In wetlands, the function is described in terms of the wetland structures and processes that allow surface water to infiltrate into the groundwater system. Adamus et al. (1991) and the expert teams developing the Washington State wetland function assessment methods (Hruby et al. 1999, 2000) concluded that the movement of water into the ground depends primarily on:

- The elevation of the wetland relative to the groundwater
- The mass and pressure of water ("pressure head") in the wetland
- The physical characteristics and frictional resistance of the sediments and strata underlying the wetland (hydraulic conductivity)

If the surface of the water in a wetland is groundwater, or the primary source of water to the wetland is groundwater (e.g., a seep), the wetland cannot recharge that groundwater. By definition, recharge occurs only if water from surface runoff infiltrates into groundwater.

The information available on the potential for wetlands to recharge groundwater is contradictory. In a review of scientific studies that quantified the hydrologic functions of wetlands, Bullock and Acreman (2003) found 32 studies that documented that recharge occurs and 18 studies where no recharge was found. Adamus et al. (1991) conclude, from an extensive review of the literature, that four site-specific conditions determine how well a wetland performs this function:

- Groundwater flow rates under the wetland (linked to hydraulic conductivity)
- The storage capacity of the wetland (linked to the pressure head of water)
- Water movement within the wetland (linked to elevation relative to groundwater and hydraulic head)
- Evapotranspiration (linked to "pressure head" of water in the wetland)

These conclusions about these site-specific conditions were more recently confirmed by Hunt et al. (1996).

Adamus et al. (1991) were unable to find any patterns among wetland types or regions of the country. They also concluded that "for recharge, adjacent undeveloped uplands are usually, but not always, more important than wetlands." This conclusion was confirmed by Bullock and Acreman (2003).

Groundwater Recharge by Wetlands of Various Classes and in Different Regions

The characteristics within a wetland that result in the recharge of groundwater are the same for wetlands in both the eastern and western parts of the state. The potential for recharge in a wetland occurs when wetlands hold back precipitation and surface flows to create ponded areas. This ponded water then infiltrates into the groundwater system because of the "head" or pressure created by the depth of water on the surface. If the hydraulic head created by upslope groundwater is greater than the hydraulic head created by the ponded water, recharge will not occur (Adamus et al. 1991).

Groundwater recharge occurs only in a subset of **depressional wetlands** and some **riverine wetlands** that impound and hold surface water. Wetland types that do not impound surface water do not have the potential to recharge groundwater (Hruby et al. 1999, 2000, Hruby 2004a,b).

A new perspective on the function of supporting baseflow

One aspect of groundwater recharge that is often attributed to wetlands in Washington is called *baseflow support*. Wetlands are assumed to augment base flows in streams during the drier seasons because of the water they store. The information available, however, indicates this assumption is not valid in most cases, and in fact wetlands may reduce baseflow because of water lost through evapotranspiration. In a review of scientific studies that quantified the hydrologic functions of wetlands, Bullock and Acreman (2003) found that 49 out of 75 studies (2/3) conclude that wetlands reduce the flow of water downstream during dry periods. Only 16 studies conclude that wetlands sustain low flows and ten studies found that wetlands had no impact on low flows.

In Washington, the teams of experts that developed the methods for assessing functions and the rating systems concurred with the majority of studies (Hruby et al. 1999, 2000, Hruby 2004a,b). Surface outflow from wetlands was not judged to be an important factor in maintaining low flows in streams in Washington State. A wetland may be in a location where groundwater is discharged, but the source of this groundwater is not within the wetland itself. Thus, the discharge is not a function of the wetland; rather it is, as reported by Adamus et al. (1991), a function of the entire groundwater system.

Given the highly seasonal rainfall patterns in the region, the teams also judged that most surface water will be discharged into streams before the late summer when low flows as biologically the most critical. Water stored in the soils of wetlands was not considered to be a factor because of the types of soils present. Wetlands on alluvial soils would not hold water long enough into the dry season to support baseflow because they are so permeable (review in Bullock and Acreman 2003). On the other hand, wetlands with organic and peat soils would hold water and not release very much of it because the hydraulic conductivity is generally very low. The hydraulic conductivity of water in peat soils ranges between 0.000001 cm/sec to as high as 0.001 cm/sec (less than 3 ft per day) (Reeve et al. 2000) depending on the structure of the peat or the mineral soil.

2.6.3 Functions Related to Habitat

This section focuses on three aspects of wetlands as habitat:

- Structures and processes found within wetlands that make them an important habitat feature of the landscape
- The number and types of vertebrate species using wetlands in the Pacific Northwest
- Important features of wetlands that meet the habitat requirements of some groups of species that are closely associated with wetlands and that were modeled in the Washington State wetland function assessment methods

The discussion is not subdivided by wetland class or domain and region of the state because habitat requirements differ widely for various species. Furthermore, habitat requirements for a single species may even differ between locations (Adamus et al. 1991). Therefore, this literature review does not attempt to identify all the life requirements of all wildlife species that use wetlands in Washington. The intent of this synthesis is to identify some of the basic structures and processes in wetlands that are important habitat features.

2.6.3.1 The Use of Wetlands by Species of Wildlife

Animals use wetlands to varying degrees depending upon the species involved. Some live in wetlands for their entire lives; others require wetland habitat for at least part of their life cycles; still others use wetlands much less frequently, generally for feeding (Johnson and O'Neil 2001). Thus, species using wetlands are often grouped by their dependency on the habitat provided by wetlands, but unfortunately there is no consistency in the terms used to describe the dependency.

For example, Adamus et al. (1991) grouped species into two categories. *Wetland-dependent species* are those that: "(a) normally use wetlands exclusively for food and cover throughout most of their U.S. range and spend most of their lifetime within wetlands, or (b) would be extirpated from a large region if all wetlands were to be filled." The latter case includes species that may use wetlands for only part of their life cycles such as amphibians and many insects. The larvae of amphibians and many insects are aquatic even though the adults migrate out of the wetlands. The species are still considered to be wetland dependent because they could not survive without the presence of wetlands. *Wetland users* are those species that use wetlands for occasionally obtaining some life requirements such as sources of drinking water, winter cover (e.g., white-tailed deer and ring-necked pheasants), or dispersal centers within urban areas (e.g., opossum) (Adamus et al. 1991).

Adamus et al. (1991) also state the following about how species use wetlands:

> *The degree of dependence by any given species on wetlands often varies greatly depending on the abundance and distribution of wetlands and on suitable alternative habitats within the region. For example, urban wetlands and riparian wetlands in the arid Southwest support species that, in other parts of their ranges, are much less likely to inhabit wetlands.*

The Washington State wetland function assessment method uses the terms *wetland dependent* for western Washington (Hruby 1999) and *wetland associated* for eastern Washington (Hruby 2000). More recently, Johnson and O'Neil (2001) have developed a grouping based on three categories that are specific to wildlife in Washington and Oregon that is based on the consensus of numerous experts in the region. These authors use the terms *closely associated*, *generally associated*, and *present* when describing the relationship between species and wetlands, and these are defined as follows:

- *Closely Associated* – A species is widely known to depend on a habitat for part or all of its life history requirements. Identifying this association implies that the species has an essential need for this habitat for its maintenance and viability.

- *Generally Associated* – A species exhibits a high degree of adaptability and may be supported by a number of habitats. In other words, the habitat plays a supportive role for its maintenance and viability.

- *Present* – A species demonstrates occasional use of a habitat. The habitat provides marginal support to the species for its maintenance and viability.

2.6.3.2 Characteristics that Make Wetlands Important as Habitat

Wetlands are among the most productive ecosystems in the world, comparable to rain forests and coral reefs (Mitsch and Gosselink 2000, Sipple 2002). As a result, wetlands support numerous species from all of the major groups of organisms—from microbes to mammals (Sipple 2002). The support they provide for these organisms includes sources of food, shelter, and refuge. All of these aspects are generalized by the term *habitat*.

General reviews of wetlands as habitat (Adamus et al. 1991, Mitsch and Gosselink 2000) conclude that physical and chemical characteristics (factors that control the suitability of a wetland as habitat) determine what plants and animals inhabit various wetlands, including:

- Climate
- Topography (landscape shape)
- Geology
- Nutrients
- Hydrologic regime (quantity and movement of water)

In addition, some of the larger organisms such as beaver and muskrats manipulate wetlands to create habitat suitable for themselves and other organisms, such as fish, amphibians, waterfowl, insects, and other mammals (Mitsch and Gosselink 2000).

Four general ecological features contribute to species richness and abundance in a landscape (Knutson and Naef 1997):

- Structural complexity
- Connectivity with other ecosystems
- Abundant food source and available water
- Moist and moderate microclimate

Wetlands have all of these attributes, especially wetlands that are linked to riparian areas and floodplains. The following sections describe each of these features in more detail.

Structural Complexity

Structural complexity is a term used to represent the variety of environmental characteristics that increase the number of niches for wildlife (Knutson and Naef 1997). These characteristics can include biological features such as a high richness of plant species or physical features such as open water, rocks, and mudflats. The interspersion in wetlands between open water and vegetation, or between types of vegetation, is important because the edges created between these elements (see Figure 2-10) increase the number of niches present (Adamus et al. 1991). Wetlands also often contain different vegetation communities within their boundaries that add structure (and therefore niches). For example, a higher interspersion of plant types in wetlands is likely to support a higher diversity of invertebrates (Dvorak and Best 1982, Lodge 1985).

Figure 2-10. Features of wetlands that increase structural complexity. This wetland has open water and plants of different heights and different types (woody, herbaceous, aquatic bed) as well as snags and woody debris.

Riparian wetland systems in the semi-arid West often provide the only structurally complex habitat in regions dominated by open land or land cleared for agriculture (Adamus et al. 1991). This has also been found to be true in the semi-arid areas of eastern Washington, especially in the areas where rainfall is less than 12 inches per year (Hruby et al. 2000). Figure 2-11 shows a wetland with high structural complexity in the semi-arid terrestrial environment of eastern Washington that otherwise does not have much complexity.

Figure 2-11. Depressional wetland in the Columbia Basin. A structurally complex ecosystem in a terrestrial environment with low complexity. The average annual rainfall at this site is 8 inches per year.

Connectivity to Other Natural Resources

Many wetlands are linked to other aquatic or terrestrial resources by surface water, riparian corridors, or by relatively undisturbed vegetated corridors. Riverine wetlands form part of riparian corridors, depressional wetlands may be part of a small stream system or may be linked by surface water, and lacustrine fringe wetlands are connected to adjacent lakes. The role that corridors play in maintaining biodiversity, however, is very complex. For some species corridors are essential to maintain populations and genetic exchange (Kauffman et al. 2001, Haila 2002, Fahrig 2003). In other cases they may reduce populations of some species because they facilitate the movement of predators or invasive species (review in Fahrig 2003). See Chapters 3 and 4 for further discussion of habitat connectivity and corridors to both aquatic and terrestrial habitats.

Abundant Food Sources

The wet and moist microclimate of wetlands and their rich soils lead to the enhanced growth of plants. Wetlands are known for their high primary productivity (production of plant material) and the subsequent movement of this "food" to adjacent aquatic ecosystems (Mitsch and Gosselink 2000).

"Wetlands can be thought of as biological supermarkets" (Sipple 2002). For example, the number of invertebrates in small seasonal wetlands can exceed 700,000 animals per square meter (Leeper and Taylor 1998). Many of these invertebrates serve as food for larger predatory amphibians, reptiles, fish, birds, and mammals (Wissinger 1999).

Moist and Moderate Microclimate

The presence of water and thick vegetation in wetlands results in a microclimate that is generally more moist and that has milder temperature extremes than the surrounding areas. These conditions provide a habitat that is desirable to many species, particularly amphibians, ungulates, and other large mammals during hot, dry summers and severe winters (Knutsen and Naef 1997).

2.6.3.3 Use of Wetlands by Vertebrates in Washington

Wetlands in the state have been shown to be critical in maintaining regional biodiversity. Although wetlands represent only 2.1% of the area of the state (Dahl 1990), over two-thirds of all terrestrial vertebrate species in Washington can be considered "wetland users" (Knutson and Naef 1997, Kaufmann et al. 2001). A comprehensive review of wildlife in Washington and Oregon (Johnson and O'Neil 2001) provides a compilation of all wildlife species found in Washington and the different habitats in which they are found. Of the 32 types of habitat identified in the review, four are specific to wetlands. Table 2-7 lists the four types of wetland habitats identified in the compilation and the number of wildlife species found in each type. Appendix 2-B lists all the species found in each type of wetland as compiled in the review.

Table 2-7. Number of wildlife species by type of wetland habitat and by their association. From O'Neil and Johnson 2001. See Appendix 2-B for definitions of the types of wetlands.

Habitat Type	Total	Closely Associated	Associated	Present	Unsure
Herbaceous wetland	228	105	90	31	2
Westside Riparian-Wetlands	256	74	145	35	2
Montane Coniferous Wetlands	148	17	101	28	2
Eastside Riparian-Wetlands	271	81	149	36	5

Reptiles and Amphibians

There are 59 species of reptiles and amphibians in Washington and Oregon. Two species of reptiles, the western pond turtle (*Clemmys marmorata marmorata*) and the painted turtle (*Chrysemys picta*), are wetland dependent. Many more species of reptiles are wetland users. On the other hand, all but one species of amphibians are wetland dependent and require an aquatic habitat for part of their life cycle (Kauffman et al. 2001). Figure 2-12 shows how many of the 59 species of reptiles and amphibians in the two states are found in three of the four types of wetland habitat.

In Figures 2-12 to 2-14 the data are from (Kauffman et al. 2001). The lists of actual species in each type of habitat and the definitions of each type of habitat are summarized in Appendix 2-B.

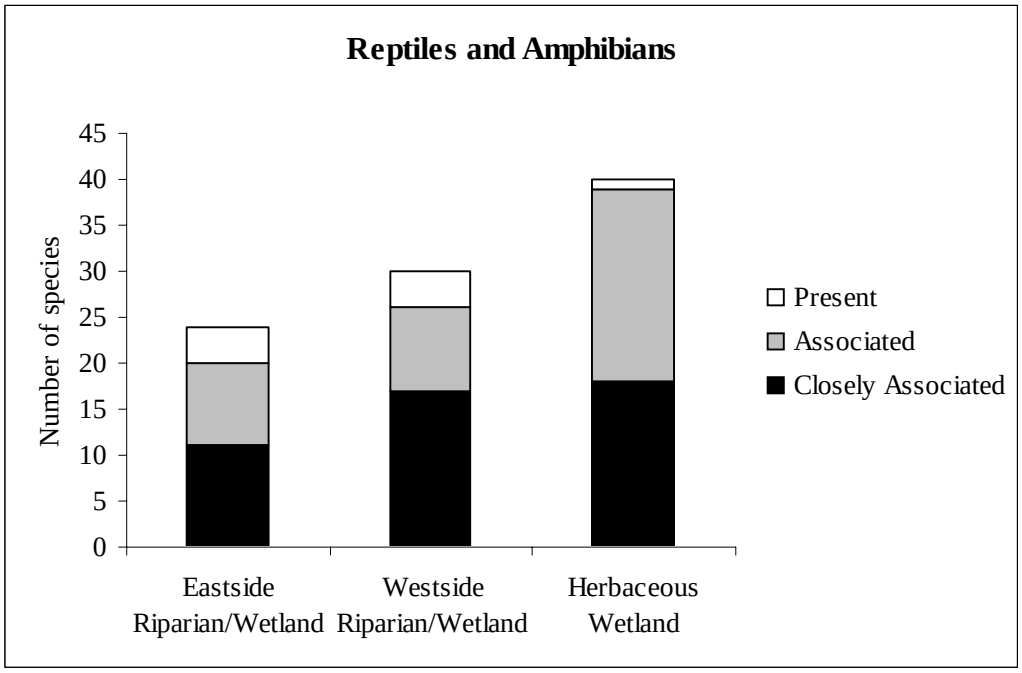

Figure 2-12. The number of reptile and amphibian species found in wetlands in Washington and Oregon. (from Kauffman et al. 2001)

Birds

Overall, 266 (72%) of the 367 species of birds in Oregon and Washington use freshwater, riparian, and wetland habitats. More striking, 204 (77%) of the 266 species of inland birds that breed in the two states do so in wetland environments (Kauffman et al. 2001). Figure 2-13 shows the number of bird species that use three types of wetlands in the region.

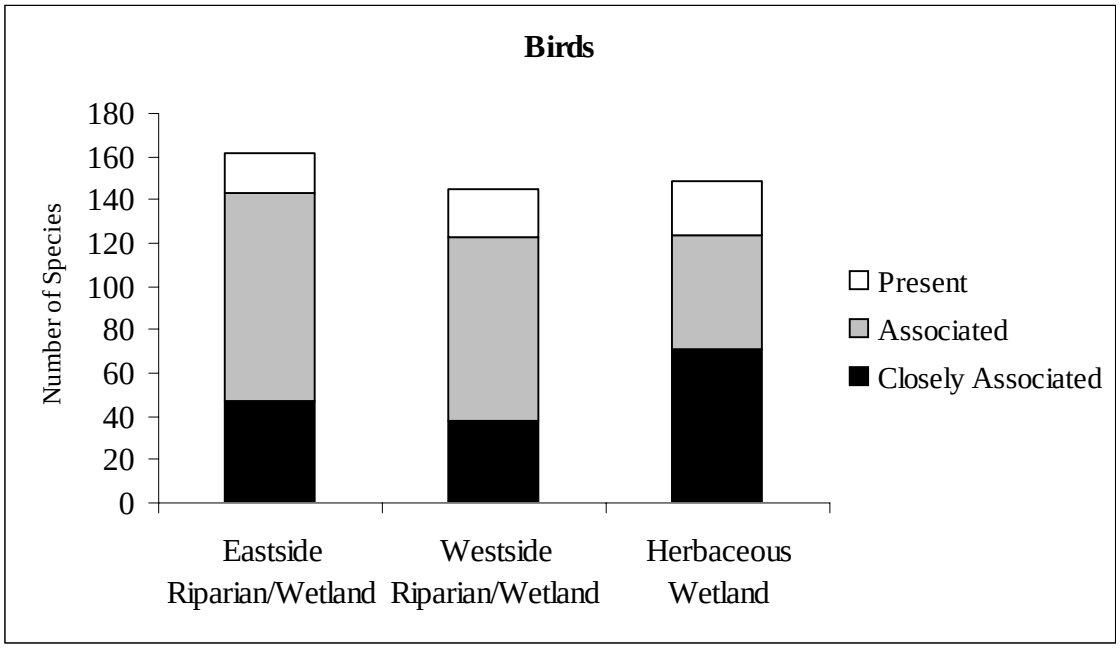

Figure 2-13. The number of bird species found in wetlands in Washington and Oregon (from Kauffman et al. 2001).

Mammals

Ninety-five of the 147 mammal species (65%) in the two states use the riparian/wetland ecosystem (Kauffman et al. 2001). All the "furbearers" (e.g., mink, otter, beaver, raccoon, etc.) use these habitats, and all but one of the big game animals (deer, elk, moose, etc. with the exception of bighorn sheep) rely on these areas for part of their habitat requirements. Figure 2-14 shows the number and degree of association of mammals to the three types of wetland habitats considered in Kauffman et al. (2001).

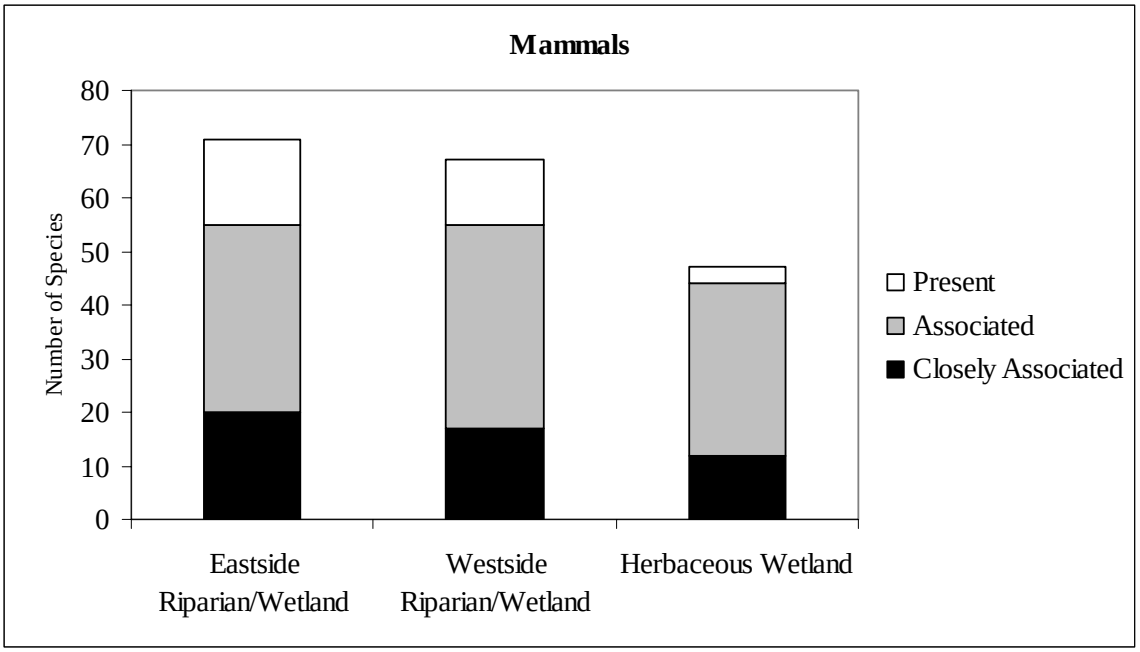

Figure 2-14. The number of mammal species found in wetlands in Washington and Oregon (from Kauffman et al. 2001).

2.6.3.4 Habitat Requirements of Some Wetland-Dependent Species in Washington

Invertebrates

Invertebrates have evolved unique adaptations enabling them to occupy most wetland habitats and most parts of the food web. In fact, wetland invertebrates can be distinguished from terrestrial and aquatic species at multiple taxonomic levels (family and genus) (Wissinger 1999). Wetlands are dominated by invertebrate families that are uniquely adapted to shallow and often fluctuating water levels (Wissinger 1999).

Wetland invertebrates are considered pivotal components of the food webs in wetlands (Mitsch and Gosselink 2000). As filter feeders, shredders, and scrapers, insects convert microorganisms and vegetation into biomass, providing much of the food for animals higher in the food web (secondary and tertiary consumers). Research focusing on aquatic invertebrates in wetlands indicates the importance of invertebrates in energy and the transfer of nutrients within aquatic

ecosystems (Rosenberg and Danks 1987, Wissinger 1999). Invertebrates have adapted to processing the plant material produced in wetlands of every type and geomorphic setting. They are considered a major link in the movement of energy in the food web of wetlands (review in Wissinger 1999).

The abundance of invertebrates in wetlands can be extremely large. Leeper and Taylor (1998) measured annual densities in excess of 700,000 organisms per square meter in shallow depressional wetlands of South Carolina.

Factors found to influence the distribution, richness, and abundance of invertebrates in wetlands include the following:

- **Water interspersed with stands of emergent vegetation** in wetlands result in high species richness of invertebrates (Voigts 1976).
- **Decaying wood** provides an important habitat for invertebrates (Maser et al. 1988).
- A **mix of plant assemblages** exhibits greater richness of invertebrate species than a single assemblage (Andrews and Hasler 1943, Dvorak and Best 1982, Lodge 1985, Balla and Davis 1995). Furthermore, the density of invertebrates varies considerably among species of submerged aquatic plants (Murkin and Batt 1987), and different invertebrate species are found on different plant species (Cyr and Downing 1988). Vegetation is a major factor shaping wetland invertebrate communities (Krieger 1992, Wissinger et al. 1999).
- **Permanent flowing water** is a habitat feature that supports a unique assemblage of invertebrate species (Needham and Needham 1962, Wiggins et al. 1980, Rolauffs et al. 2001). Furthermore, the invertebrates in flowing permanent channels are an important resource for many other aquatic species such as fish (Needham and Needham 1962).
- **Marked seasonal changes in water regime** in wetlands result in higher richness of invertebrate species compared to wetlands with little water level fluctuation (Balla and Davis 1995).
- **Water regime** in wetlands is an important factor for individual species of invertebrates. Factors associated with water regime include: permanence of surface water, predictability of drying and filling, seasonal timing of drying and filling, duration of dry and wet phases, and the harshness during dry and wet phases(temperature, salinity, oxygen levels) (reviewed in Wissinger 1999).

Not much is known about invertebrate distributions in different soil surfaces within a wetland. However, data from rivers, streams, and lakes show that the local invertebrate species have preferences for specific surfaces (Gorman and Karr 1978, Dougherty and Morgan 1991). In streams it is well known that the composition of midges (chironomids) is strongly affected by characteristics of the sediment surface (McGarrigle 1980, Minshall 1984).

Amphibians

Amphibians are a vertebrate group that, in the Pacific Northwest, includes wetland-breeding frogs and salamanders. Both the richness and abundance of amphibians in wetlands indicate that they

are important in wetland food webs (Leonard et al. 1993, Hruby et al. 1999). Some native species only breed for a short time in wetlands and then live in uplands as adults. Other species are found in or close to wetlands throughout the year. However, the eggs and larvae of all wetland-breeding species require water for development (Hruby et al. 1999).

Other information known about amphibians in wetlands includes the following.

- The **presence of buffers and undisturbed uplands and forest cover** leading to other wetlands or to upland habitat is critical. Relatively undisturbed migration routes between a wetland and upland feeding and hibernation sites are important for many amphibian species (Heusser 1968, Berven and Grudzien 1990, Beebee 1996). Moreover, dispersal routes for recolonization are critical when populations are eliminated by random processes including drought (Pounds and Crump 1994), disease (Bradford 1991), or pollution (K. Richter, PhD. personal communications 2000), or when populations produce insufficient offspring to permanently occupy a site (Gill 1978a, 1978b, Sinsch 1992). Finally, inbreeding is minimized when the amphibians within a wetland are members of a population that extends across several wetlands (Gulve 1991, 1994, Pechmann and Wilbur 1994).

- **Conditions in the buffers** of a wetland are especially important in providing cover to amphibian females and to newly metamorphosed animals. Female red-legged frogs (*Rana aurora*), Northwestern salamanders (*Ambystoma gracile*) (K. Richter, PhD. personal communication, 2000), and long-toed salamanders (*A. macrodactylum*) (Beneski et al. 1986, Leonard and Richter 1994) generally wait in buffers near wetlands until environmental and biological conditions are favorable to spawning. They then enter wetlands during one or a few nights to spawn, thereafter quickly retreating to the cover provided by buffers. Buffers are important to the tiger salamander (*A. tigrinum,* a species found in eastern Washington) seeking shelter in rodent burrows during the first days following emigration from ponds in which they are born (Loredo et al. 1996).

- Most species of amphibians select **areas with interspersed vegetation and exposed water** in which to lay eggs (K. Richter, PhD. personal communication 2000). Most species of amphibians generally avoid both exposed water and densely vegetated sites, instead selecting habitats with an interspersion of both features (Strijbosch 1979, Ildos and Ancona 1994).

- **Stable water levels** provide optimum habitat conditions for amphibians from spawning through hatching. Water level fluctuations are known to have a significant influence on amphibians (Richter 1996, 1997). Most species of amphibians in temperate climates minimize exposure of eggs to fluctuating depths and temperatures by both spawning at mid-depth and by submerging eggs below the surface (Richter 1997). Amphibian egg development also depends on permanent or partial submergence. In most Puget Sound species stable water levels occurs from mid-December through mid-May. Although mean water level fluctuations exceeding approximately 8 inches (20 cm) have been correlated to decreased amphibian richness in wetlands , experiments by Azous and Richter (1995) suggest that extended drops of more than approximately 3 inches (7 cm) from the time of egg laying through hatching may harm the Northwestern salamander.

- **Vegetation structure**, particularly plant shape and stem diameter, rather than the species of the plant has been suggested to be most important to salamanders. Wetland surveys and controlled field studies of several Northwest salamanders confirm that distinct stem widths are preferred (Richter 1997).

Anadromous Fish

Anadromous fish are those that spend all or part of their adult lives in salt water and return to freshwater streams and rivers to spawn. There are 12 species of anadromous fish in the Pacific Northwest (PSMFC 2001), but not all are regular users of wetlands.

The Pacific Northwest salmonids (species of the genus *Oncorhynchus*) have recently been the focus of much research because of the status of some species as threatened or endangered. The most common anadromous species that uses wetlands is the coho salmon (*Oncorhynchus kisutch*). Other anadromous fish noted in wetlands found in side channels, or old oxbows, of rivers and streams (off-channel wetlands) include cutthroat trout (*O. clarki*) and steelhead (*O. mykiss*) (Peterson 1982).

It is not the intent of this review to summarize all the information available on the habitat needs of salmonids. Some of the most important habitat structures in wetlands that have been found to be important for anadromous fish are summarized below:

- The **presence of ponded or impounded surface water** that is either seasonal or permanent is critical. "Slope" wetlands in Washington are the only class of wetlands that do not have the potential to provide habitat for anadromous fish because, by definition (Brinson et al. 1995) they do not have ponded or impounded surface water that is either seasonal or permanent.

- A wetland must have a **surface water connection** to a salmon-bearing stream or river if fish are to enter or exit the wetland (Hruby et al. 1999).

- **Interspersion between land and water** in a wetland is important because the contact zones between exposed water and vegetation provide protection from wind, waves, and predators, and may provide natural territorial boundaries (Golet and Larson 1974).

- Anadromous fish need a certain **water depth** for optimum habitat conditions. Narver (1978) observed juvenile coho moving into areas with water depth over approximately 18 inches (45 cm) and lower velocities (6 inches [15 cm] per second) when temperatures decline below approximately 41^{o}F (7^{o}C). Beaver ponds and off-channel areas with similar depths also provide habitat (Reeves et al. 1989). Survival and growth of overwintering fish may be maximized in systems that contain both shallow pools and deeper ones (Peterson 1982).

- **Cover** provided by wetlands is important for salmonids**.** Overhanging vegetation provides both temperature control and protection from predation. McMahon (1983) reported the need for streamside vegetation for shading. Small coho juveniles tend to be harassed, chased, and nipped by larger juveniles unless they stay near the bottom, obscured by rocks

or logs (Groot and Margolis 1991). Cover for salmonids in wetlands can be provided by (Giger 1973):

- Overhanging vegetation
- Submerged vegetation
- Submerged objects such as logs and rocks
- Floating debris
- Deep water
- Turbulence
- Turbidity (the assumption seems to be that cloudy water reduces the visibility of fish in open water where birds may prey on them)

Resident Fish

Fish that do not migrate out of wetlands are considered "resident fish." Many different fish species use wetlands and it is not practical to list all that occur in Washington's wetlands.

Before the late 1800s, the only resident freshwater game fish living in Washington State were trout, char, whitefish, burbot, and squawfish. Since then there has been a widespread and often indiscriminate introduction of game species from other parts of the nation (Washington State Department of Fish and Wildlife 1999b).

Some of the characteristics in wetlands that provide habitat for resident fish include the following.

- Resident fish, like anadromous fish, need a **range of water depths** for different parts of their life cycles (Hruby et al. 1999). Shallow waters provide refuge for young fish, while the deeper waters provide refuge for the larger adults. Varying water depths also provide different potential food sources since they are host to different populations of plants and invertebrates (see the earlier discussion of invertebrate habitat). Olympic mud-minnows rear in wetlands with water only a few inches deep in floodplains (R. Ziegler, Washington State Department of Fish and Wildlife, personal communications 2003).
- **Shorelines between exposed water and vegetation** provide protection from wind, waves, and predators, and may provide natural territorial boundaries (Golet and Larson 1974).
- **Overhanging vegetation** provides both temperature control and protection from predation (McMahon 1983).
- **Large woody debris** plays an important role in the Pacific Northwest, creating and enhancing fish habitat (Bisson et al. 1987).

Birds That Are Closely Associated With Wetlands

Bird species that are *closely associated* with wetlands are those that depend on part or all of its life requirements; these include food, shelter, breeding, or resting. Kauffman et al. (2001)

reviewed the literature and found a very high richness and abundance of birds in wetlands of the Pacific Northwest. They found that:

> *All 23 species of waterfowl that breed regularly in the western U.S. south of Alaska do so in riparian and wetland environments. Similarly, all 14 western species of waders, a group consisting of cranes, rails, herons, and ibises, depend on riparian and wetland habitats for most of their life cycles. Shorebirds, which include stilts and avocets, sandpipers, and plovers are typically dependent on freshwater, riparian, and wetland habitats. Interior wetlands (i.e., east of the Cascades) also provide crucial stopover habitat for 37 species during migration.*

A review of the specific habitat requirements of all birds using wetlands is beyond the scope of this document. General characteristics of wetlands and their buffers that provide good habitat for wetland-dependent birds include the following:

- The **condition of the wetland buffer** is an important characteristic for bird habitat. Trees and shrubs provide screening for birds, as well as providing additional habitat in the buffer itself (Johnson and Jones 1977, Milligan 1985).

- The **width of the buffer** as well as its condition is important (see Chapter 5 for a more detailed discussion of the use of buffers by birds).

- **Snags** are a source of cavities and perches for wetland-associated birds. Several species of birds use already existing cavities for nesting and/or refuge locations. Dead wood attracts invertebrates and other organisms of decay, which in turn provide a food source for many species of birds (Davis et al. 1983).

- Some bird species may require **several habitat types** such as open water and grasslands in close proximity to aid their movements from one type to another (Gibbs et al. 1991, Hunter 1996).

- **Embayments and peninsulas** in a wetland with open water provide "micro-habitats" for certain species that require hiding cover or those seeking security within a more enclosed system (U.S. Department of the Interior 1978).

- The **proximity of a wetland to open water or large fields** increases its utility to migrant and wintering waterfowl. If there is strong connectivity between relatively undisturbed aquatic areas, the suitability of a wetland as waterfowl habitat increases (Gibbs et al. 1991).

- **Open water of varying depths** provides greater diversity of foraging habitat for a greater variety of water birds (U.S. Department of the Interior 1978).

- A **full canopy can limit access** to open water in a wetland because birds have difficulty flying in and out. This may be best illustrated by great blue herons (*Ardea herodias*), which will be reluctant to fly down to a body of water if the tree canopy above is totally closed because rapid escape may be difficult or impossible (U.S. Department of the Interior 1978).

Mammals That Are Closely Associated With Wetlands

For the purpose of this review it is not practical to synthesize the specific habitat requirements of all mammal species using wetlands. The richness of mammal species using wetlands can be very high. Kauffman et al. (2001) report that 79 mammal species east of the Cascades and 69 on the west side use riparian wetlands. The wetlands associated with stream corridors characteristically have greater species richness than upland sites and provide habitat for some species that are not found elsewhere. About half of the species using riparian wetlands in the Pacific Northwest breed and feed in them (Kauffman et al. 2001.)

The following bullets summarize some general information about the characteristics of wetlands that provide good habitat for four mammal species that were modeled as wetland dependent in the Washington State methods for assessing functions (Hruby et al. 1999). These species include the beaver (*Castor canadensis*), muskrat (*Ondatra zibethicus*), river otter (*Lutra canadensis*), and mink (*Mustela vison*).

- Wetlands with a **relatively undisturbed buffer** are important to these four species (and others) because the buffers:
  - Minimize disturbance (Allen and Hoffman 1984, Burgess 1978)
  - Provide habitat for prey species and food sources for mammals (Allen 1983, Dunstone 1978, Brenner 1962)
  - Provide cover from predators (Melquist et al. 1981)
  - Allow den sites for resting and reproduction (Allen 1983)
- Beavers prefer a **seasonally stable water level** (Slough and Sadleir 1977). Large fluctuations in water levels may also affect the suitability of a wetland for muskrats (Errington 1963). Wetlands subject to heavy spring runoff or flash floods that rapidly raise the water level may cause flooding of burrows (Errington 1963).
- For beavers and muskrats, **water depth must be of sufficient depth. For beavers the water must be deep enough** to accommodate lodges and bank dens and to allow free movement from the lodge to food caches during the winter. For example, freezing of the food cache is a limiting factor on beaver and muskrat survival in the Columbia Basin (J.Tabor, Washington State Department of Fish and Wildlife, personal communication 2000). Freezing of a pond to the bottom can be disastrous to muskrat populations (Schmitke 1971). Deep water will also provide protection from predators (Easter-Pilcher 1987). In the Columbia Basin beavers and muskrats need at least 4 feet (1.3 m) of permanent water to allow access to food caches during the winter when the surface is frozen (Hruby et al. 2000).
- **Vegetated corridors** leading to and from wetlands are considered an important feature in assessing the suitability of a wetland as habitat for wetland dependent mammals (Hruby et al. 2000). Dispersal is a fundamental process in regulating populations among these and other mammals (Kauffman et al. 2001).

- Muskrats and beavers use **persistent emergent cover** for security and feeding (Errington 1963). Allen (1983) believes that beavers prefer herbaceous vegetation over woody vegetation during all seasons, if available.

- **Interspersion of vegetation and open water** is an important characteristic of wetlands as habitat for mammals. High interspersion rates increase the abundance of prey for mink and river otter (i.e., muskrats, water birds, fish) (King 1983). Food abundance and availability appeared to have the greatest influence on habitat use by river otter in Idaho in studies by Melquist and Hornocker (1983). Classic studies of muskrats by Dozier (1953) and Errington (1937) indicate that optimum muskrat habitat is 66% to 80% of the wetland in emergent vegetation with the remainder in open water.

2.6.3.5 Habitat for Plants

Relatively few plant species of the thousands on Earth have adapted to the harsh conditions in wetlands. Major stressors are lack of oxygen, salt, and water level fluctuations in an environment that is neither fully aquatic nor terrestrial (Mitsch and Gosselink 2000). These strong selective pressures have produced a group of plant species that is unique to wetlands and whose maintenance has become an issue in regional biodiversity (Gibbs 2000). Furthermore, wetlands can provide habitat for a wide range of other plant species when conditions are not as harsh. Of the 2969 plant species found in Washington, 1515 (or 51%) have been found in wetlands (FEMAT 1993).

All wetlands provide the four basic requirements for plant growth (space, water, light, and nutrients) to some degree. Differences can be found among wetlands in the number of plant species they contain. Recent research has been focused on the characteristics of wetlands that affect plant richness, as summarized below:

- **Specific water regimes**, such as permanent inundation, seasonal flooding, or saturation, result in unique plant communities (Mitsch and Gosselink 2000).

- The **duration of individual flooding events** is important in separating plant communities because the duration affects germination of seeds in different ways (Casanova and Brock 2000).

- The **water regime** in a wetland can either limit the number of species present or enhance it, depending on types of water level fluctuations and physical energy of the water regime (Mitsch and Gosselink 2000).

- Plant richness in a wetland generally follows the ecological theory that maximum richness occurs at **intermediate levels of environmental stress** (Johnson and Leopold 1994). For example, water level fluctuation is an environmental stress (Mitsch and Gosselink 2000). Wetlands with large water level fluctuations, therefore, would be expected to have fewer plant species than those with moderate water level fluctuations. On the other hand, wetlands with very small water level fluctuations (low stress) would also be expected to have fewer plant species.

- Wetlands with **different water depths** tend to have higher richness than those with fewer (Hruby et al. 1999). Observations show that the distribution of species within a wetland is primarily a function of water depths (Spence 1982 as cited in van der Valk et al. 1994).

- The **proximity of other wetlands** as a source of seed (Brock et al 1994, Brown 1998).

2.6.3.6 Supporting Food Webs (Primary Production and Export)

Wetlands are known for their high primary productivity (i.e., production of plant material) and the subsequent export of this organic matter to adjacent aquatic resources. The exported organic matter provides an important source of food for most downstream aquatic ecosystems (Mitsch and Gosselink 2000).

Plant material produced in wetlands breaks down into smaller and smaller particles and becomes increasingly nutritious due to the activity of bacteria, fungi, and protozoa (Sipple 2002). This decomposed plant material, including the various microbes that colonize it, feeds many small aquatic invertebrates and small fish. These invertebrates and fish then serve as food for larger predatory amphibians, reptiles, fish, birds, and mammals (Sipple 2002).

The following summarizes general characteristics of wetlands that have high production and provide excellent support for aquatic food webs.

- In general, wetlands **where water flows through the system** have higher levels of primary production and export than those where water is impounded without leaving (Mitsch and Gosselink 2000).

- The **water level fluctuation** as well as movement of water mentioned above through the wetland and its **soils** is one of the most important determinants of primary productivity (Mitsch and Gosselink 2000).

- Performance of this function requires both that **organic material** is produced and that a mechanism is available to move the organic matter to adjacent or contiguous aquatic resources (Hruby et al. 1999).

2.6.4 Summary of Key Points

- The residence time of water in the wetland and filtering by wetland vegetation are major processes influencing removal of sediments, phosphorus, and toxics from surface water. Wetland vegetation typically removes 80% to 90% of sediment from runoff. Wetlands with seasonal inundation or saturation have conditions that promote removal of nitrogen from surface runoff. In order for a wetland to provide functions that improve water quality, however, surface water containing pollutants must first enter the wetland.

- The capacity of a wetland to store surface water affects its ability to reduce peak flows, as do the amount of flow from the upper watershed that enters the wetland and the amount of woody vegetation present. Reducing peak flows helps to decrease downstream erosion.

- Only wetland types that impound surface water have the potential to provide groundwater recharge.
- Wildlife species can be *wetland dependent* or *wetland users*. Wetland-dependent species (such as amphibians) require a wetland for at least part of their life cycles. Wetland users (such as deer) come to wetlands for such needs as water or cover.
- The characteristics of wetlands that provide habitat depend on species and life stage. Characteristics that are important for many species include vegetation structure, water depth, water level fluctuation, buffers, snags, and connections to other habitats and wetlands in the landscape.
- Wetlands have high productivity of plant material. Decomposed plant material can be exported downstream, providing food for insects, fish, and other organisms in the food web.

2.7 Chapter Summary and Conclusions

The functions of wetlands are things that wetlands "do." They represent the many interactions possible among the different components of the environment found in wetlands. There are many interactions that occur in wetlands and they occur at many scales. In general, however, functions are grouped into three broad categories: 1) biogeochemical interactions, 2) hydrologic interactions, and 3) interactions that maintain food webs and habitats for plants and animals.

The primary factors that control wetland function are climate, geomorphology, the source of water, and the movement of water. These factors affect wetland functions directly or through a series of secondary factors including nutrients, salts, toxic contaminants, soils, temperature, and the connections created between different patches of habitat. The factors that control wetland functions interact with each other and there are many feedback loops. A number of conceptual models have been developed to help visualize and understand the complexity of the interactions between environmental factors, environmental processes, and wetland function.

The major environmental factors of geomorphology, source of water, and the movement of water are the basic characteristics used to classify wetlands in Washington into groups of wetlands that have similar functions. These groups can be expected to perform these functions in similar ways. Freshwater wetlands in Washington are divided, based on how they function, into two domains, five regions, and six classes.

The environmental factors that control the structure and functions of a wetland occur at both the landscape scale and the site scale. For example, riverine wetlands will be affected to a great degree by processes operating at the scale of the entire watershed of the river. Depressional wetlands will be subject to processes that occur only within the basin that contributes surface or groundwater to the wetland.

The most important factors that control functions at an individual site may occur somewhere else in the landscape. Information about factors that control functions at the larger scale is still evolving. The importance of the environmental factors that occur at the larger, landscape scale,

however, should not be minimized for lack of information. Ongoing research is continually strengthening our understanding of these critical factors.

The links between wetland functions and the landscape have been well described by the National Academy of Sciences (National Research Council 1995):

> *Individual wetlands function to a large degree through interaction with the adjacent portions of the landscape and with other wetlands. For example, wetlands whose principal source of water is groundwater depend on that water infiltrating in the surrounding uplands. If these uplands are paved, clear-cut, or farmed, the amount of water recharge is significantly reduced and the wetland may dry up or become smaller. No single wetland or aquatic site could support anadromous fish. The connections between individual wetlands, aquatic systems, and terrestrial systems are critical to the support of many species. Furthermore, flood control and pollution control are determined by the number, position, and extent of wetlands within watersheds. Thus, the landscape gives proper context for the understanding of some wetland functions.*

An understanding of wetland functions for the purposes of managing and protecting them will require knowledge of how the major controls of functions change or are impacted by humans at all scales. We need to understand how climate, topography, and the movement of water, nutrients, sediment, etc. are affected by human activities in the entire watershed, as well as in the immediate vicinity of the wetland. Chapter 3 describes the environmental disturbances caused by different human uses of the land. Chapter 4 then carries this information forward to discuss how the disturbances caused by human activities affect specific functions of wetlands.

Chapter 3

Environmental Disturbances Caused by Human Activities and Uses of the Land

3.1 Reader's Guide to this Chapter

In Chapter 3, the discussion shifts from wetland functions and the environmental factors that control the performance of functions to the major disturbances created by human activities and uses of the land and water. In this context, a *disturbance* is an event that changes an environmental factor that controls wetland functions.

3.1.1 Chapter Contents

Major sections of this chapter and the topics they cover include:

Section 3.2, Introduction to Human-Caused Disturbances provides an overview of how human land uses change the dynamics and structure of the ecosystems by creating various types of disturbances. The section provides a general overview of how human activities affect the movement and quality of water and connections between habitats across the landscape.

The chapter continues with separate sections for four of the major types of human land uses in Washington State (agriculture, urbanization, logging, and mining) and how they cause disturbances. The different uses of the land by humans are divided into these four categories because most of the literature found discusses the disturbances and impacts of human activities in these terms.

Each major land use is addressed in a separate section, as follows:

Section 3.3, Disturbances Caused by Agriculture, discusses the changes in the physical structure of wetlands such as conversion to fields or pasture, changes in water regime such as changes to the amount and fluctuation of water, and the input of nutrients, salt, sediment and contaminants caused by agriculture.

Section 3.4, Disturbances Caused by Urbanization, discusses the changes urbanization has made, causing a loss of wetlands as well as changes to the water regime in watersheds. It describes how this land use has resulted in sedimentation, increase in nutrients, input of contaminants, and fragmentation of habitat.

Section 3.5, Disturbances Caused by Forest Practices, refers the reader, after a brief summary, to another synthesis that summarizes the literature on the disturbances created by logging.

Section 3.6, Disturbances Caused by Mining, discusses the increased level of heavy metals and acidity in surface waters that results from mining.

Section 3.7, Chapter Summary and Conclusions, ties together the major concepts presented in the chapter in a tabular form. Also, the disturbances caused by each of the four land uses are summarized.

3.1.2 Where to Find Summary Information and Conclusions

Each major section of this chapter concludes with a brief summary of the major points resulting from the literature review on that topic in a bulleted list. The reader is encouraged to remember that a review of the entire section preceding the summary is necessary for an in-depth understanding of the topic.

For summaries of the information presented in this chapter, see the following sections:

- Section 3.2.6
- Section 3.3.11
- Section 3.4.9

As previously mentioned, Section 3.7 provides a summary and conclusions about the main themes synthesized from the literature and presented in this chapter.

3.1.3 Sources and Gaps in Information

There is abundant data on some of the topics related to wetlands and the effects of land uses on water quantity, water quality, and some habitat issues. For example, the Puget Sound Wetlands and Stormwater Management Research Program was one important source of scientific information on how changes in land uses affect the physical, chemical, and biological factors that control wetland functions in the lowlands of Puget Sound. The research program has published numerous articles in scientific journals and has summarized much of the information developed in a book by Azous and Horner (2001).

In contrast, information on the effects of agricultural practices in the Pacific Northwest, especially in eastern Washington, is limited. Most studies originate from the prairie pothole region of the United States, the high mountain West, or California. The literature related to agriculture from outside the Pacific Northwest region has been included in this synthesis when it was judged to be relevant to Washington.

No scientific studies were found that examined the question of whether some wetlands in eastern Washington existed before the onset of irrigation projects. Research has been conducted by Adamus on irrigated agricultural lands from the high basin country of Colorado (Adamus 1993), but may not be germane to eastern Washington because soils and the surface geology are different. However, this study is included in the section on the influence of irrigation on wetlands because it discusses some of the issues that are relevant to the Columbia Basin.

3.2 Introduction to Human-Caused Disturbances

Human activities on the land increasingly represent a fundamental source of change in the global environment (Dale et al. 2000). Alterations to land use and land cover can often change the environmental factors that control functions within a wetland. Modifications in the environment that cause changes in how ecosystems function are called *disturbances*. Pickett and White (1985) define *disturbance* as "any relative discrete event in time that disrupts ecosystem, community, or population structure and changes resources, substrate availability, or the physical environment."

Disturbances to ecosystems are commonly viewed negatively as a disruption of equilibrium in an ecosystem. A growing science based on non-equilibrium theory, however, indicates that disturbances are an essential ecological process. They are necessary at some level of intensity and periodicity for the long-term maintenance of most, if not all, ecosystems (Averill et al. 2003). Disturbance occurs as a continuum from frequent intervals of low intensity to infrequent occurrences of high intensity (Pickett and White 1985). The average frequency of a given disturbance is inversely proportional to its intensity (Waldrop 1992). Large, intense, disturbances are rare and small ones frequent. Ecosystems have evolved in response to specific regimes of disturbances that have recurred over millions of years (Averill et al. 2003).

The disturbances caused by humans, however, often differ from those that occur naturally. They occur at different scales, different intensities, and different geographic locations (Dale et al. 2000). As a result ecosystems tend to respond in unexpected ways to human activities and many functions that ecosystems provide change or are diminished. Scientists sometimes use the term *stressor* to distinguish those disturbances that have a major impact on an ecosystem from those that maintain the usual structure and function of an ecosystem (see for example Adamus et al. 2001, Laursen et al. 2002). For the purposes of this discussion, however, only the term *disturbance* is used to simplify the discussion. All the disturbances discussed herein are stressors considered to have major impacts on ecosystems, and they are not the ones that maintain the existing structure and functioning in an ecosystem.

3.2.1 The Link between Wetland Functions, Human Land Uses, and Changes in Wetlands

In terms of wetlands and their functions, a disturbance can be considered as a condition or event that changes one of the environmental factors that control wetland functions. For example, nutrients are a factor that controls wetland functions. If nutrients from residential lawns flow to a depressional wetland that has limited nutrients, such as a bog, the excess nutrients can change the dominant plants in the bog and its habitat structure. In this case, the addition of nutrients that are in excess of those found in the absence of human activities is a disturbance on the functions of the wetland.

This example illustrates how changes in land use can influence large-scale environmental processes, resulting in disturbances to the factors that control wetland functions. It also illustrates how the topics discussed in Chapters 2, 3, and 4 of this volume are linked:

- The movement of nutrients throughout a basin, as described in the example, is one of several environmental factors that control wetland functions. These factors and the way in which they control wetland functions are the subject of Chapter 2.
- The maintenance of residential lawns is an example of a human activity that may affect the movement of nutrients in a basin. The application of excess nutrients (fertilizer) creates a disturbance when the nutrients flow from the lawn into a bog. This chapter (Chapter 3) describes how different kinds of human activities and uses of the land create environmental disturbances.
- When the excess nutrients reach the bog, they cause a change in its plant community and its habitat structure because the plant communities are adapted to a low-nutrient, acidic environment. Chapter 4 describes how disturbances caused by human land uses result in changes to wetland functions.

Figure 3-1 reviews the connection between the factors that control wetland functions, human-caused disturbances, and the functions of wetlands.

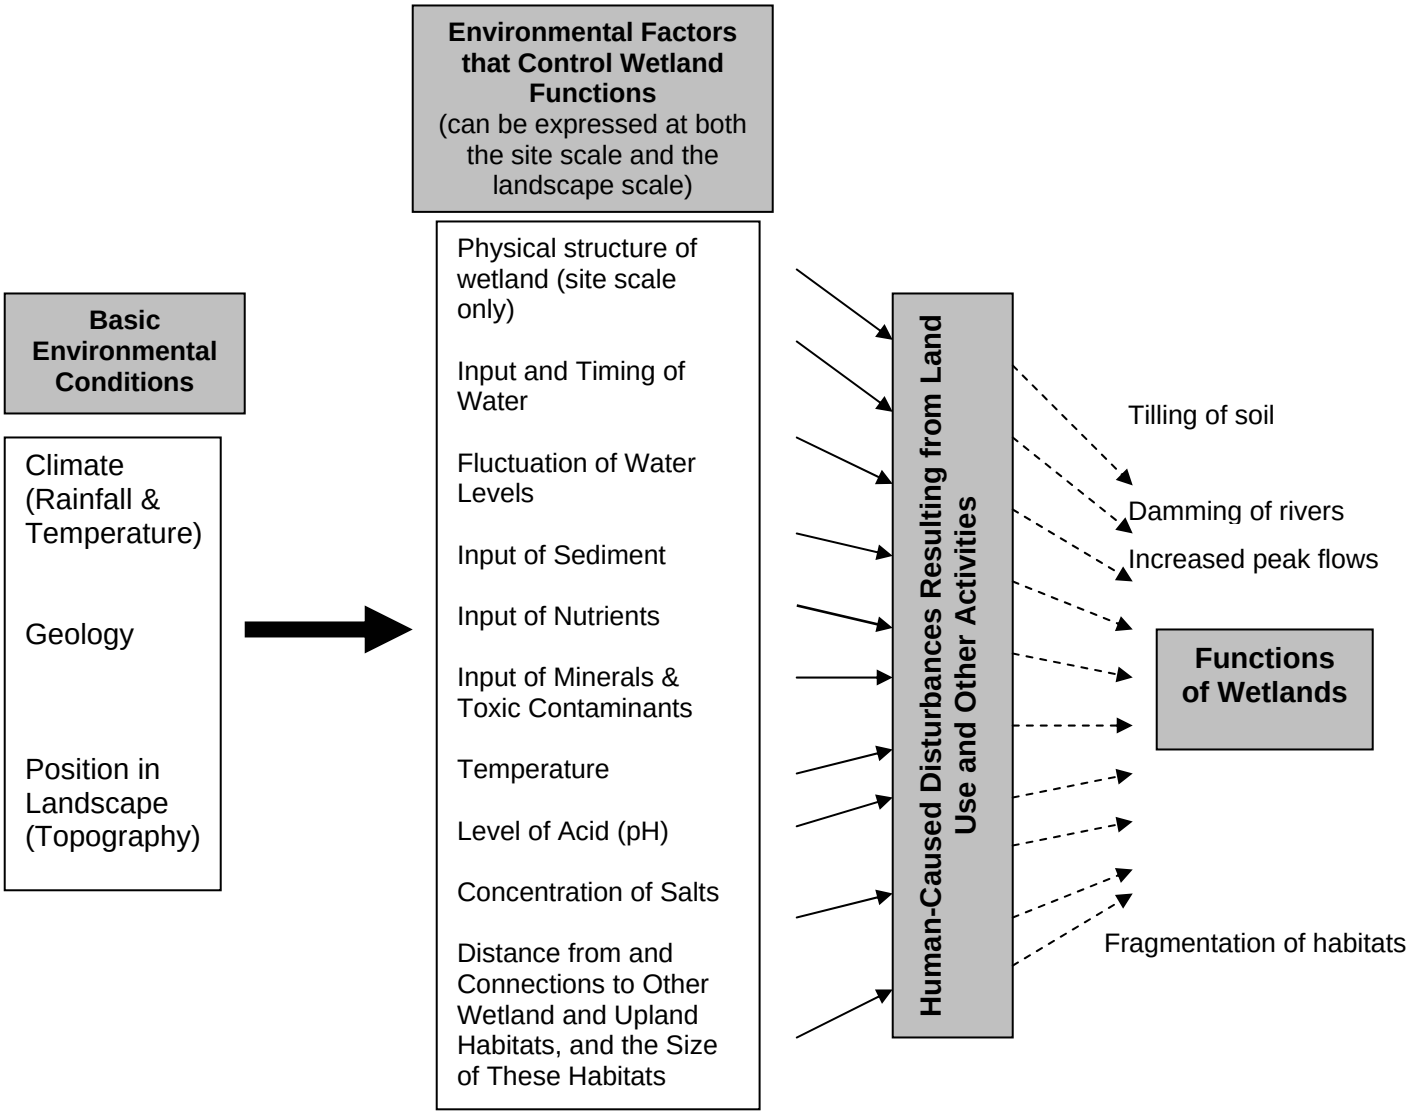

Figure 3-1. Diagram summarizing some major environmental factors that control functions of wetlands and how they interact with human-caused disturbances.

The basic environmental conditions establish and determine the factors that control the functions of wetlands. The controls can occur at both the landscape and site scales. Human activities cause disturbances that affect these controls in many different ways and thereby alter the performance of wetland functions. The figure gives some examples of the disturbances. This figure is the same as that in Chapter 2, Figure 2-3.

3.2.2 Types of Disturbances Resulting from Human Land Uses

Many different types of disturbances have been identified in the literature. For the purposes of organizing the information in this chapter, the list developed by Adamus et al. (2001) and shown in Table 3-1 is used because it was developed specifically to address impacts to wetland functions. Table 3-1 lists the types of disturbances that can impact wetlands and the scale at which the disturbances can occur. Many disturbances

that result from human uses of the land can occur over large areas such as basins and sub-basins (called the landscape scale), as well as in the wetland itself and in its immediate vicinity (called the site scale).

Table 3-1. Summary of human-caused disturbances and the scale at which they can occur.

Disturbance	Scale of Disturbance
Changing the physical structure within a wetland (e.g., filling, removing vegetation, tilling soils, compacting soils)	Site
Changing the amount and velocity of water (either increasing or decreasing)	Landscape and site
Changing the fluctuation of water levels (frequency, duration, amplitude, direction of flow)	Landscape and site
Changing the amount of sediment (increasing or decreasing the amount)	Landscape and site
Increasing the amount of nutrients	Landscape and site
Increasing the amount of toxic contaminants	Landscape and site
Changing the temperature	Mostly site
Changing the acidity (acidification)	Landscape and site
Increasing the concentration of salt (salinization)	Mostly site
Fragmentation (decreasing area of habitat and its spatial configuration)	Landscape
Other disturbances (noise, etc.)	Landscape and site
This table is a synthesis of the information presented by Adamus et al. (2001) and in the literature review done for this document.	

3.2.3 Disturbances to the Movement of Water at the Landscape Scale

The movement and sources of water in the landscape are two critical factors controlling how wetlands function. Many human land uses change the movement and sources of water, thereby creating a disturbance that affects the performance of functions in wetlands. The following provides some background on how human activities result in disturbances to the movement and sources of water.

The literature is quite clear that the frequency, timing, and duration of water in the landscape determine the presence of a wetland and the functions that it provides (see Chapter 2). How water enters a wetland, how long it is present, and the depths to which it is impounded all influence the functions that a wetland can provide or perform (Brinson 1993a, Mitsch and Gosselink 2000).

Surface and subsurface water flows through the landscape within "drainage systems." These drainage systems are often called basins, sub-basins, watersheds, or river basins depending on the size of the area. In this document, drainage systems are generally referred to using one of two terms:

- ***Watershed*** - A geographic area of land bounded by topographic high points in which water drains to a common destination.

- ***Contributing basin*** - The geographic area from which surface water drains to a particular wetland.

Booth (1991) succinctly summarizes the concept of a drainage system as follows:

> *Drainage systems consist of all of the elements of the landscape through which or over which water travels. These elements include the soils and the vegetation that grows on it, the geologic materials underlying that soil, the stream channels that carry water on the surface, and the zones where water is held in the soil and moves beneath the surface. Also included are any constructed elements, including pipes and culverts, cleared and compacted land surfaces, pavement and other impervious surfaces that are not able to absorb water at all.*

The movement and routing of water above and below the surface is the primary force in transporting nutrients, sediment, salts, and contaminants, and this in turn affects the functions provided by wetlands (Naiman et al. 1992). Water moves (or carries) sediment, nutrients, and energy throughout a watershed (Naiman et al. 1992). Changes in the amount of water, as well as in the frequency and fluctuations of water volumes, can alter how sediments, nutrients, and toxic contaminants come into a wetland. Changes in the movement of water resulting from human activities at the scale of the landscape can therefore have severe impacts on wetland functions throughout a watershed.

The following subsections provide background on how water moves in undisturbed landscapes as well as those that have been changed by human activities. The purpose of this discussion is to provide a context for understanding how human activities and uses of the land create the disturbances discussed later in the chapter.

Terms used to describe water regimes: hydrology vs. hydroperiod vs. hydrologic

Hydrology and hydroperiod are often used interchangeably to mean how water moves. *Hydrology*, as defined by Webster, is "the scientific study of the properties, distribution, and effects of water in the atmosphere, on the earth's surface, and in soil and rocks." The term hydrology means the study of how water moves.

Hydroperiod (not defined by Webster) is commonly used to refer more precisely to the periodicity of water; the timing (seasonal or otherwise) and duration of water's presence or absence within a particular aquatic feature, such as a wetland. It is "the seasonal occurrence of flooding and/or soil saturation, encompassing the depth, frequency, duration and seasonal pattern of inundation" (Azous et al. 2001). Mitsch and Gosselink (2000) define hydroperiod as "the seasonal pattern of the water level of a wetland . . . a hydrologic signature of each wetland type." Hydroperiod, in this context, refers to seasonal changes in wetland water level conditions caused by regular annual changes in water availability. This should be differentiated from the water level fluctuations driven by single or serial storm events.

Hydrologic is an adjective derived from the word "hydrology." It refers to the properties, distribution, and effects of water. Thus a term such as "hydrologic processes" refers to the environmental processes that involve the properties, distribution, and effects of water.

In this document, "hydroperiod" is used to refer to the pattern of water movement in a particular wetland or type of wetland. The term "hydrology" has been retained when direct quotes from sources use that term even if it has been misused. "Hydrologic" is used when an adjective is needed to describe the patterns of water movement.

3.2.3.1 Movement of Water in Undisturbed Landscapes

In undisturbed conditions, very little of the precipitation falling on the ground ends up in surface runoff, even in areas of high annual rainfall such as the Pacific Northwest. Areas with natural vegetation provide high rates of interception, infiltration, and evapotranspiration (Ziemer and Lisle 1998). The water either drips off leaves to the soil below; flows down the stems, leaves, and bark to the soil; or evaporates into the air, never reaching the ground.

Water that infiltrates into permeable surfaces either moves downgradient as shallow groundwater, infiltrates into a deeper water table, or is taken up by plant roots and transpired back into the atmosphere. Shallow groundwater flows downgradient through the pore spaces in the soils until it surfaces in a stream, wetland, or swale, sometimes in the form of a seep or spring.

Precipitation falling onto naturally impervious surfaces (e.g., bedrock), however, flows along the surface. Precipitation also flows along the surface if the soils become saturated and cannot hold any more water.

3.2.3.2 Movement of Water in Disturbed Landscapes

Human activities on the land change the movement of water across and through the landscape such that there are significant changes in runoff patterns and hydroperiods in a watershed (Booth 1991, Vought et al. 1995, Azous and Horner 2001). Surface runoff, rather than infiltration, comes to dominate water flows, as shown conceptually in Figure 3-2. The movement of water in a landscape can be altered by any of the following conditions:

- Removal of vegetation
- Compaction of soil (through grazing, earthwork, lawns, or playfields)
- Reduction in size of soil particles or the spaces between particles (through tilling or grading)
- Reduction in the organisms that aerate the soil
- Placement of drain tiles, ditching, road cuts, utility lines
- Construction of impervious surfaces
- Construction of dams and reservoirs

These conditions result from human land uses such as agricultural conversion, urbanization, and forest practices (Dunne and Leopold 1978, Booth 1991, Euliss and Mushet 1996). The disturbances from specific land uses to the movement of water and its sources are described later in this chapter. Information on the resulting impacts on wetland functions is synthesized in Chapter 4.

Removing vegetation allows precipitation to reach the soil surface faster, and therefore soil saturation occurs more rapidly. As soils become saturated, additional precipitation accumulates more rapidly on the surface and moves as sheet or surface flows. When soils are compacted, the precipitation cannot enter the soils readily and surface water accumulates more rapidly. Loss of permeability in the soil can persist even after compacted soils become vegetated as urban lawns, playfields, and in some agricultural conditions (Dunne and Leopold 1978).

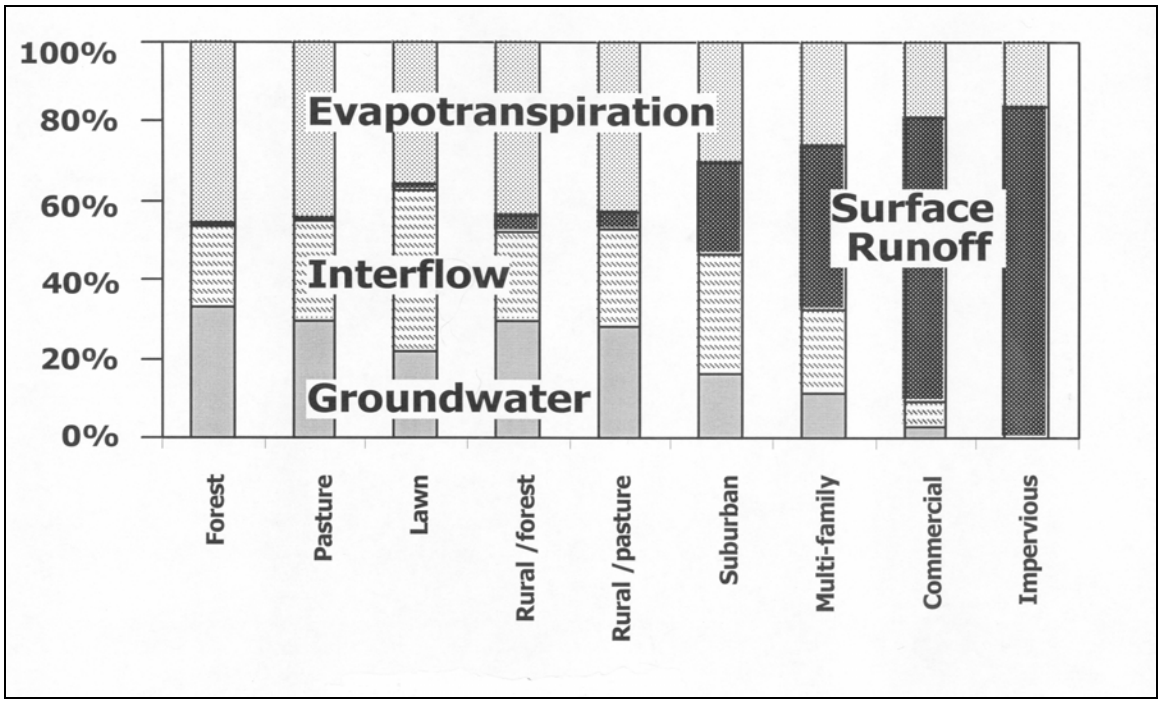

Figure 3-2. Changes in the proportion of groundwater, interflow, evapotranspiration, and surface runoff with different types of land cover in western Washington (Beyerlein 1999; reprinted with permission).

Under any of these conditions, runoff essentially becomes surface flow. Water flowing along the surface carries sediment and any other dissolved or adsorbed materials downgradient more rapidly than if the water is allowed to infiltrate in undisturbed soils (Ziemer and Lisle 1998). Studies in the Puget Sound region found that peak flows increase during storms as a result of urban development, but that the annual mean flow decreases (Konrad 2000).

In general, alteration of water flow in uplands results in a "shortening" of the path that water would naturally follow on its route through a watershed. It reduces the residence time of water in the ground and in bodies of surface water, such as streams or wetlands, within the watershed. On the other hand the construction of dams and weirs has resulted in the retention of water and a reduction in water velocity once the water reaches a stream or river.

Changing the water flow in uplands also results in increased rates and volumes of stormwater and changes the timing of stormwater entering aquatic systems. This can have numerous effects on aquatic systems as described in Section 3.4.2 on the effects of urbanization. For example, these changes circumvent or reduce:

- The removal of nutrients, pathogens, and toxics in the soil
- The filtering of sediment from surface flows through vegetated buffers and wetlands
- The reduction of downstream peak flows

3.2.3.3 The Role Of Impervious Surface In Changing Water Regimes

According to research throughout the country and in the Pacific Northwest described below, the degree of alteration in hydrologic processes and the subsequent impacts to aquatic habitats (including wetlands) is governed by the percent of impervious area and the percent of forested cover within a watershed. When soil is covered with impervious surfaces there is no opportunity for infiltration. All precipitation that falls on an impervious surface becomes surface water which flows downgradient.

Research in western Washington generally indicates that increases in the amount of impervious cover within a watershed can result in significant impacts to the habitat structure and function of freshwater aquatic systems (Azous and Horner 2001). Reinelt and Taylor (2001) discovered that 20% impervious cover in upstream development increased the peak and volume of stormwater runoff to the point that it began to dominate the hydroperiod of downstream wetlands. However, some scientists have concluded that trying to identify a specific threshold may not be accurate. As stated by Dr. Richard Horner "We are thoroughly convinced that there is no threshold; deterioration begins immediately and progresses at a rapid rate as soon as any amount of urban development begins" (Horner, University of Washington, personal communication 2004).

Defining and assessing impervious surface

The term *impervious surface* as used in the literature and in this document means more than just a hard impermeable surface such as an asphalt parking lot. There are many actions humans take that reduce the permeability of soils, and these are included in the calculations of "percent impermeable surface." For example, compacted soils found in lawns and landscaped areas function just as impervious surfaces do during storm events (May 1996).

Total impervious area (TIA) is sometimes challenging to assess without high-resolution aerial photographs and accurate GIS mapping capabilities (especially in watersheds with extensive forested coverage). Reinartz and Warne (1993) found that using road density as an indicator of basin impervious area resulted in findings nearly identical to those resulting from estimation of imperviousness from aerial photographs.

Reinelt and Taylor (2001) concluded that removing as little as 3.5% of the forested cover in a rural, low-density residential area resulted in changes in the pattern of water movement in the basin. Looking at percent forested cover in the Puget Sound Basin; Booth et al. (2002) have determined that natural hydrologic processes are maintained if 65% of a watershed remains in a forested condition. Because each watershed has different physical, chemical, and biological characteristics and patterns of impervious cover, the threshold at which aquatic resources experience significant effects will vary.

Table 3-2 summarizes additional findings on the effects of impervious cover on various biological characteristics of aquatic resources. As noted previously, specific impacts to wetland functions are described in Chapter 4.

Table 3-2. Summary of findings on the impacts of impervious cover.

Reference	Impacts to:	Key Finding
Booth (1991)	Fish habitat; channel stability	Channel stability and fish habitat quality declined rapidly with over 10% impervious cover
Taylor (1993)	Wetland plants and amphibians	Mean annual water level fluctuations are inversely correlated to density of plants and amphibians. Sharp declines occur when impervious cover exceeds 10%
Steedman (1988)	Invertebrates	Negative correlation between biologic integrity and increasing development at 209 streams. Degradation started at 10% impervious cover

3.2.3.4 The Role Of Dams In Changing Water Regimes

The construction and operation of dams affects the movement of water across large areas of the landscape. Regardless of their purpose, all dams trap particles to some degree and most alter the flood peaks and seasonal distribution of flows (Kondolf 1997). Dams disrupt the continuity of processes that occur at the landscape scale. Areas where water flowed fast may now have slow water movement and vice-versa (Kondolf 1997). In cases where water is transferred for irrigation or other purposes the reductions in discharge may greatly influence the hydrophysical conditions in the floodplain (Fjellheim and Raddum 1996).

There are four major aspects of changes to water regimes that result from the construction of dams (Bunn and Arthington 2002). These are:

- Reduction of the variability in flows
- Loss of some seasonal fluctuation in the wet/dry cycle
- Erratic daily patterns in the flow below hydroelectric dams
- Conversion of river and floodplain water regime (and habitat) to a lake water regime

Thus dams can change the water regime in a riverine and floodplain system to one that was not there previously, nor that could have been easily created by non-human factors.

For example, there are 211 major dams in the Columbia River Basin, 34 of which are on the main stems of the Columbia and Snake Rivers. The water levels in the reservoirs behind the dams operated by the Army Corps of Engineers rise and fall on a schedule unrelated to natural fluctuations. Levels in reservoirs may drop suddenly on a daily basis. The 211 dams also significantly reduce and slow the movement of water (Northwest Environmental Advocates, http://www.advocates-nwea.org/programs/U.html, accessed October 7, 2004).

3.2.4 Disturbances to the Quality of Water at the Landscape Scale

Two principal mechanisms have been documented to describe how land uses in a watershed change water quality in that watershed:

- Changes in hydroperiod increase erosion and sedimentation (Booth 1991, Booth and Reinelt 1993, Horner et al. 1996)
- Human uses of the land generate pollutants that are then transported into aquatic systems (Reinelt and Horner 1995)

Larger volumes of water, moving at faster rates, scour channels and cause rills in unvegetated soils. Moving water picks up and transports sediment and the pollutants associated with sediment particles. In addition, research shows that water flowing across the ground surface tends to pick up and convey dissolved nutrients and toxics directly into receiving waters (Young et al. 1980, Emmett et al. 1994, Gilliam 1994, Brenner 1995, Reinelt and Horner 1995, Vought et al. 1995, Crosbie and Chow 1999, Sheridan et al. 1999, Azous and Horner 2001).

Pollution conveyed by surface runoff (called *non-point-source pollution* by the U.S. Environmental Protection Agency) has been identified as the dominant source of pollutants in surface water. Non-point-source pollution is not discharged from the "end of a pipe" such as a large factory. Instead it is caused by sediment, metals, excess nutrients, and bacteria from a variety of dispersed sources (Reinelt and Horner 1995) such as stormwater, contaminated runoff from urban settings, agricultural runoff, and construction runoff (Baker 1992). These pollutants can have numerous impacts on wetlands and their functions as described in Chapter 4.

3.2.5 Disturbances to Habitats at the Landscape Scale (Fragmentation)

Human activities within a landscape often break up environment into small patches of habitat that are separated by roads, buildings, or tilled fields. The breaking up of the environment into habitat "patches" separated by areas altered by human land uses is a disturbance that is called *fragmentation*. Habitat fragmentation consists of both the reduction in the area of the original habitat and a change in spatial configuration of what remains (Haila 2002).

Suburban and urban development, farmlands, roads, railroads, powerline corridors, and other land uses cause various kinds and degrees of fragmentation (Heinz Center for Science 2002). These are discussed in more detail in subsequent sections of this chapter. In addition, human activity can create landscapes that are less varied than the landscapes historically present. Particularly in the West, natural fires create a patchy landscape, where forest and grasslands are intermingled in a mosaic. Fire suppression and the large

fires that result after long periods of suppression can create broad expanses of very similar vegetation (Heinz Center for Science 2002).

All environments, with or without human activities, are fragmented to some degree and are subjected to continuous change due to "natural" causes. As a result, no straightforward standard is available for assessing human-caused fragmentation. Furthermore, different ecosystems and the species they support experience the effects of fragmentation in variable, even contradictory ways (Haila 2002). For example, the breaking up of a certain habitat into patches may increase the populations of certain species by keeping predators from moving between patches. Such patches, however, will reduce the populations of predators because their access to prey will be reduced (Fahrig 2003).

The effect of human-caused fragmentation needs to be considered at different spatial and temporal scales, and the relevant scales will vary across species, geographic regions, and types of environment (Haila 2002). The types of fragmentation caused by the major land uses is described in this chapter, and the impacts of fragmentation on the functions of wetlands are described in Chapter 4.

3.2.6 Summary of Key Points

- Many human land uses change the movement and sources of water in a watershed, thereby creating a disturbance that affects the performance of functions in wetlands.
- In general, alteration of water flow by human uses of the land results in a "shortening" of the path that water would follow on its route through a watershed. It reduces the residence time of water in the ground and in the bodies of surface water, such as streams or wetlands, within a watershed.
- Changes in the amount of water and the frequency and fluctuations in water volumes can also change how sediments, nutrients, and toxic contaminants come into a wetland.
- Research in western Washington generally indicates that increases in the amount of impervious cover within a watershed can result in significant impacts to the habitat structure and function of freshwater aquatic systems.
- Two principal mechanisms have been documented to describe how land uses in a watershed change the water quality in that watershed: (1) land uses increase erosion and sedimentation, and (2) human uses of the land generate pollutants that are then transported into aquatic systems.
- Human activities within a watershed often break up the nevis and habitats into small patches and this disturbance is called fragmentation.

3.3 Disturbances Caused by Agriculture

This section describes the types and severity of disturbances that can be caused by agricultural practices. As mentioned previously, these disturbances can, in turn, affect factors that control wetland functions and are discussed in Chapter 4.

Wetlands have historically been some of the first places on the landscape that were used for agriculture. In western Washington, sites with flat topography suitable for agriculture were often located in river or stream floodplains. Many areas of these floodplains were wetlands with high water tables that persisted late into the growing season. Most early descriptions of Northwest rivers tell of valleys so wet that trails followed 'the borders of mountains' (Sedell and Luchessa 1982). Much of the flooding was a result of beaver activity that modified the flood plain and created areas where sediments could accumulate. Because the bottom land had accumulated fine silts and organic matter of alluvial origin, the land was fertile and drained early in the development of Oregon and Washington (Sedell and Luchessa 1982).

Agricultural practices play a significant role in influencing water movement in many regions of Washington. However, much of the research on wetlands in Washington over the last 10 years has been on the effects of urbanization. Although some of the consequences and effects of agriculture and urbanization may be the same or similar, others may be quite different. For example, agricultural practices in some parts of the state such as the Columbia Basin may have resulted in the creation of wetlands, or the expansion of pre-existing wetlands through the introduction of water from irrigation (Foster et al. 1984).

Cranberry growing operations in Washington are a type of agricultural land use that affects wetlands. However, cranberry production is limited to very small areas along the southern Washington coast in Pacific and Grays Harbor counties. The types of impacts that occur from conversion of wetlands to cranberry production are very different from other types of agricultural impacts. Due to the limited area affected, and time and funding limitations, this synthesis does not attempt to address the effects of cranberry production on wetlands in the state.

3.3.1 Loss of Wetlands and Changes to the Physical Structure of Wetlands from Agricultural Practices

Agriculture disturbs the physical structure of wetlands directly through conversion of the wetland to fields or pasture that often leads to the elimination of wetlands themselves. Conversion activities include filling or tilling, draining through tiles or channels, or removing the wetland vegetation and planting upland vegetation or crops. For example, tilling the soil within a wetland will disturb its soil structure (Nowak 1980, Hayes 1995). Livestock grazing in riparian wetlands also has well documented effects on the structure of plants and soils in wetlands as described below. Another example of disturbing the physical structure of riparian wetlands is the building of dams for irrigation since water

flow is a major determinant of the physical habitat in aquatic systems (Bunn and Arthington 2002). The disturbances created by dams are discussed in Section 3.2.3.4.

In studying riparian wetlands, Chappell et al. (2001) concluded that wetland loss in western Washington has been caused primarily by conversion to land development and agriculture. Although Chappell et al. (2001) do not estimate the loss that can be attributed to the different types of land uses, Bell (2002) found that 40% of the losses to peat wetlands in King County between 1958 and 2000 could be attributed to agriculture.

A recent study in the Willamette Valley (an urbanizing area similar to the Puget Sound Area) found that wetlands continue to be lost due to agriculture. Approximately 2.1% of the wetland area (3,800 hectare) was lost, and of this 70% was associated with agriculture, 6% to urbanization, and 24% to other causes (Bernert et al. 1999).

Outside of Washington, tremendous loss of wetland acreage has been attributed to agricultural filling, draining, and ditching in the prairie pothole regions of North America (Tiner 1984, Turner et al. 1987, Bardecki 1988). Researchers in Canada estimated 73% to 95% of the original wetlands in the area studied had been lost to agricultural conversion by the late 1960s (Snell as quoted in Bardecki 1988). Their work in Canada parallels the findings of Tiner (1984) that up to 87% of wetland loss in the United States was related to agricultural practices.

The literature on the effects of grazing on the physical structure of wetlands is focused primarily on riparian habitats, including riparian wetlands. Only a few of the studies found on this topic are located in the Pacific Northwest. However, much of the literature from the Midwest and even some from Australia may also be relevant because the types of disturbances caused by grazing are not geographically isolated. Many of the studies focused on riparian areas without differentiating between riparian upland and riparian wetland areas.

In summary, the effects of grazing in riparian areas include (Armour et al.1991, Busby 1979):

- Loss of the structure provided by vegetation
- Trampling and related sloughing and erosion of streambanks
- Shallower and wider streams

The effects of grazing on riparian vegetation vary significantly depending on the frequency and intensity of grazing (Clary 1995, Clary et al. 1996, Jansen and Robertson 2001). Soil compaction and a reduction in ground-cover vegetation lead to erosion and greater volumes of runoff from the compacted areas. Also, as native plant species are trampled and grazed and shading is reduced, there is more opportunity for establishment of species that can tolerate disturbance (see Chapter 4).

3.3.2 Increased Amounts of Water in Wetlands Resulting from Agricultural Practices

Water availability was a limiting factor for agricultural practices in the areas of low rainfall until the U.S. Bureau of Reclamation began intensive damming and irrigation projects in the early 1900s (Lemly 1994). Since then, irrigation practices have been influencing the presence of wetlands and their functions in areas in the rain shadow of the Olympic Mountains and the arid parts of eastern Washington. Most of the scientific literature concerns western states such as Colorado and Wyoming as well as Washington east of the Cascade Mountains. No information was found regarding the disturbances caused by irrigation practices on the Olympic Peninsula.

Irrigation can increase the amount of water at or near the surface (Adamus 1993). This may result in the creation and maintenance of wetlands in locations where they did not previously exist. New wetland areas have formed because of the sustained higher water table from seepage out of irrigation reservoirs, irrigation channels, and irrigation runoff. Leakage from irrigation channels and ditches often allows the formation of wetlands along channel margins or immediately downslope of ditches. Excess irrigation water applied to fields that exceeds the capacity of the soils to absorb water ("tailwater") may also form wetlands in low-lying areas that collect excess runoff. Tailwater also includes the spillage that occurs during operation of the irrigation system (Adamus 1993). For example, the Potholes Reservoir area within the Columbia Basin Irrigation Project contains wetland complexes that exist because of high groundwater caused by the high water levels in the reservoir (Tabor, Washington State Department of Fish and Wildlife, personal communication 1998).

Studies in Wyoming by Peck and Lovvorn (2001) support the idea that irrigation can be significant in creating and supporting wetlands and the biotic communities that depend upon them. The authors noted that 65% of inflows into wetlands in the Laramie Basin were derived from irrigation waters. They reached this conclusion by studying the loss of wetlands when irrigation practices were made more efficient (this is discussed further in Section 3.3.3).

In some instances, pre-existing wetlands experience deeper water for longer durations in the summer due to runoff from irrigation. Wetlands in the Potholes Reservoir that may have been seasonally inundated have become permanently inundated because of irrigation (Creighton et al. 1997).

In Colorado, Adamus (1993) differentiated between types of irrigation-related wetlands during a study of bird use of wetlands associated with irrigation waters. His work is cited here for relevant insights into the complexities of wetlands associated with irrigation.

However, due to physiographic and climatic differences between the Colorado Plateau and Washington, not all of his findings may be directly relevant to irrigated agricultural lands of the state. He identified the following types of irrigation-related wetlands:

- ***Irrigated wetlands*** are those that are created on farmed lands as the result of the duration and frequency of inundation from irrigation waters. The wetlands are most often created on the farmed lands within the actual zone of irrigation.
- ***Enhanced wetlands*** are those that are enlarged or their hydrologic regime extended (i.e., longer inundation or saturation) as the result of runoff from irrigation waters.
- ***Induced wetlands*** are those that develop as a result of irrigation runoff (from the farmed lands) where wetlands did not exist previously. These wetlands may or may not be located on the lands that are irrigated, but the source of the runoff water that creates these wetlands is excess runoff from irrigated fields.

Adamus (1993) also noted:

> *However, even after visiting a site it is difficult to determine conclusively the primary source of water that sustains a wetland. Irrigated wetlands, as considered by this project, can range from wetlands that are completely supported by irrigation runoff at all seasons, to wetlands that exist naturally but for which any measurable amount of their water originates from irrigation, however indirectly (e.g., through seepage or raised water tables). …determining whether the primary water source of a wetlands is irrigation-related in many cases requires considerable judgment, and no highly replicable approach exists that is applicable to all situations.*

Adamus (1993) determined that the following are *not* adequate criteria to distinguish the water source and, therefore, whether the major source of water to a wetland is irrigation:

- **Seed species richness.** Wetlands that are the result of irrigation water and are more than a few decades old are difficult to distinguish from pre-existing wetlands based on the species richness of the seed bank.
- **Organic content of soils.** Organic material is not an appropriate indicator of water origin. Organic detritus likely accumulates at different rates based on a variety of influencing factors. Much of the organic detritus appears to mineralize by the end of the growing season.
- **Presence of large willows and black cottonwoods.** A lack of large mature stands of black cottonwood and willows is also not an indicator of pre-existing vs. irrigated systems. Cottonwood stands may have been harvested or may never have become established. Anecdotal information concludes that cottonwood regeneration may not occur as frequently in irrigated wetlands due to overgrazing and the effects of flood management.

In the Wyoming setting studied by Peck and Lovvorn (2001), salinity of groundwater was also a factor in wetlands receiving shallow groundwater inputs from irrigated fields. Vegetation and biotic communities in the wetlands were correlated to both the water availability and the relative salinity of waters reaching wetlands. In summary, "…different irrigation practices have contrasting effects on a range of wetland types. These effects will change seasonally to impact different organisms with varying life histories, flooding requirements, and salinity tolerances" (Peck and Lovvorn 2001). The effects of changes in salinity are discussed in Section 3.3.8.

3.3.3 Decreased Amounts of Water in Wetlands Resulting from Agricultural Practices

Creighton et al. (1997) note that extensive areas of the landscape in the Columbia River Basin of eastern Washington have been altered by irrigation and the building of dams. One result of irrigation projects, they note, was "a sharp reduction in the amount of water available to native wetlands." In some instances sources of fresh water for wetlands, not resulting from irrigation, were diverted for agricultural uses and less water reached the wetlands.

In Wyoming, Peck and Lovvorn (2001) investigated the potential consequences of increasing efficiency in irrigation practices by lining ditches and using sprinkler systems (rather than flooding the fields). The authors noted that 65% of inflows into wetlands in the Laramie Basin were derived from irrigation waters. Therefore, with increased efficiency of water used for irrigation, the presence of wetlands in irrigated arid lands could decline. (The Wyoming data may be relevant to eastern Washington although the underlying geology and irrigation practices may not be identical.)

In California, the drought of 1985 through 1992 resulted in implementation of greater water conservation measures and therefore a decrease in the production of irrigation tailwater. There was a subsequent decrease in the volume of water reaching wetlands (Creighton et al. 1997).

Lower water levels in a wetland can also result from the direct ditching and draining for agricultural purposes. In this case the water entering the wetland is not reduced, rather it is shunted through the wetland and the storage capacity of the wetland is diminished. The ditching may be so effective that the area becomes upland. If, however, the draining is only partial the wetland may remain, but with lower water levels and probably a reduced area. The literature review did not disclose any information on how many wetlands in Washington may be impacted in this way.

3.3.4 Increased Fluctuations of Water Levels in Wetlands Resulting from Agriculture

The findings of Euliss and Mushet (1999) in North Dakota on the effects of agriculture on water level fluctuations in wetlands are probably significant for wetlands in the arid

grasslands of the Columbia Basin. These areas have similarities in precipitation and geologic patterns. These authors found that the hydroperiods for temporary, seasonal, and semi-permanent wetlands were all significantly affected by agricultural practices within the wetland's contributing basin. There was a three-fold increase in water level fluctuations of wetlands within tilled agricultural landscapes (average 5.5 inches [14 cm] fluctuation) compared to those surrounded by natural grasslands (average 1.6 inches [4 cm] fluctuation). The authors concluded, "Tillage reduces the natural capacity of catchments to mitigate surface flow into wetland basins during precipitation events, resulting in greater water level fluctuations in wetlands with tilled catchments."

3.3.5 Increased Input of Sediment Resulting from Agriculture

Tillage and grazing adjacent to a wetland or in a watershed can disrupt the soil, creating a source of sediment for surface runoff to transport downstream into wetlands and other aquatic systems. In addition, ditching wetlands in agricultural areas increases the rate of water movement by removing or reducing vegetation that acts to decrease the velocity of water. Unvegetated channels and ditches may be the source of sediment through increased erosion within the ditch (Brown 1988).

Baker (1992) compared sediments in agricultural runoff to those of wastewater plant effluent. He found that agricultural runoff can have suspended solids in the range of 100 to 1,000 milligrams per liter (mg/l), compared to less than 30 mg/l for wastewater that had received secondary treatment. Baker (1992) also found that non-point-source pollution from agricultural lands is driven by storms. It is therefore highly variable in extent and timing. He noted that in agricultural settings large storms can increase the sediment load by two to three orders of magnitude in a year, while the loads in wastewater discharge remain relatively consistent.

Wind-borne sediments that are eroded from tilled fields also generate high sediment loads to wetlands and streams in eastern Washington. The U.S. Department of Agriculture estimates that about half of the total farmland in Washington lost more than 2 tons of soil per acre per year through the action of wind in 1997. About 10% of the total farmland lost more than 10 tons per acre per year (Natural Resources Conservation Service 1997). By adding up the estimates of erosion rates and area that is farmland, it can be estimated that in 1997 about 15 million tons of topsoil were lost through wind erosion from fields in the state.

Sediment will eventually be transported into rivers and streams or deposited in wetlands. Wetlands found in depressions are often the low points in a landscape and will receive sediments that fall in the surrounding areas. The field teams that are calibrating both the methods for assessing wetland functions and the Washington State Wetland Rating System have observed wind-blown sediments in many wetlands of eastern Washington that were several inches deep.

3.3.6 Increased Input of Nutrients Resulting from Agriculture

In the United States the export of phosphorus and nitrogen from agricultural land can be three times higher for phosphorus and 12 times higher for nitrogen than from forested lands (Omernik 1977). Many of these nutrients are transported to wetlands, streams, rivers, and lakes because they are washed out of fields or infiltrate into groundwater. In Washington State, Williamson et al. (1998) found elevated levels of nutrients in the groundwater below irrigated fields on the Columbia Plateau. Their assumption is that the source of these nutrients is their application to fields above the groundwater.

The changes in the input of nutrients as a result of agriculture are illustrated by a study in Estonia in eastern Europe that documented what happened when agricultural fertilizers were no longer placed on agricultural lands. There was a four-fold to 20-fold decrease in pollutants associated with agricultural runoff after the collapse of agricultural collectives and the subsequent decline in the application of commercial fertilizers and manure (Mander et al. 2000). Based on 10 years of data (1987 through 1997), the researchers determined that total nitrogen, total phosphorus, biochemical oxygen demand (BOD), and sulfate all declined significantly with the demise of agricultural practices in the contributing watersheds. Forested portions of the watersheds upstream of the agricultural lands did not experience measurable changes in water quality parameters, eliminating the possibility that climatic change was the cause.

3.3.7 Increased Input of Toxic Contaminants Resulting from Agriculture

Several authors have identified agriculture across the country as one of the primary causes of non-point-source pollution in aquatic systems (Brenner 1995, Reinelt and Horner 1995, Thurston 1999). Agricultural chemicals are used to control noxious weeds, insect pests, and damaging fungi and bacteria.

Agricultural chemicals applied to fields enter downstream aquatic resources such as wetlands through three primary pathways (Neely and Baker 1985):

- Adsorbed to sediment particles
- Dissolved or suspended within surface flows
- Dissolved within subsurface drainage

Farming practices and the type of chemicals used determine how the pollutant is transported into wetlands. For example, some herbicides applied to corn are water soluble. Neely and Baker (1985) reported that water flowing across crop residue left after harvesting may wash off remnant herbicides. The concentration of such an herbicide in wetlands downgradient of a corn field may increase as a result. Similarly, Donald et al. (1999) documented that wetlands in the Canadian, prairie-pothole region receive high levels of pesticides when pesticides are applied to fields prior to significant

rains (precipitation totaling more than 2 inches [50 mm] after application). Another study, in California's Central Valley, found that surface water runoff from irrigated fields could have elevated levels of pesticides and herbicides if there had been aerial application of the chemicals or a recent land-based application (Lemly 1994).

Subsurface drainage may also contain pollutants at low levels. Lemly (1994) reported that subsurface waters from irrigated fields had low levels of herbicides or pesticides. These substances were removed from the water column through adsorption as the water filtered through the soils before draining into the subsurface collection system. Williamson et al. (1998) found elevated levels of pesticides in the groundwater below irrigated fields on the Columbia Plateau.

3.3.8 Increased Levels of Salt Resulting from Agriculture

Agricultural practices in irrigated areas can increase the salt content of water in a watershed or in areas immediately adjacent to a field. This means that wetlands receiving water from irrigated areas may also be subject to higher salt concentrations.

The soils in dry areas have developed in an environment of limited rainfall and significant periods of drying. In these areas the rate of evapotranspiration is higher than rainfall, and this draws water from below the ground's surface and causes many soluble minerals to accumulate in the upper soil horizons (Caltech 2003).

Soluble salts in irrigation water will be deposited in soils near the root zones of plants because much of the water in arid regions is lost by evaporation rather than downward transport. This salinization occurs with nearly any type of irrigation. Even if the irrigation water is only slightly saline, repeated cycles of evaporation lead to build-up of toxic salt levels in the soil (Caltech 2003). Thus, irrigation return waters are often high in salt content (Adamus et al. 2001) and this may impact wetlands that receive runoff from irrigation.

3.3.9 Fragmentation of Habitat Resulting from Agriculture

No information specific to fragmentation, the disruption of the connections between wetlands and between wetlands or other habitats, resulting from agricultural activities was found in the literature. It can be hypothesized, however, that such fragmentation has occurred because agricultural practices have fragmented habitats in general (Dale et al. 2000, Fahrig 2003). The direct loss of wetlands through conversion to uses such as agriculture increases fragmentation by removing "patches" of wetlands in the landscape. The conversion of wetlands to agricultural uses is discussed in the beginning of this section.

3.3.10 Other Disturbances Resulting from Agriculture

Several other types of disturbances that have been attributed to agricultural activities:

- Alteration of soils
- Construction of roads
- Noise
- Invasion by exotic plant and animal species

These disturbances are not discussed in detail in this chapter because little information was found describing how agricultural practices create these disturbances. The impacts of these disturbances, however, have been documented and are summarized in Chapter 4.

3.3.11 Summary of Key Points

- Agriculture may affect wetlands directly through conversion of the wetland to fields or pasture. This is often done by direct filling or tilling, by draining through tiles or channels, or by removing the wetland vegetation and planting upland vegetation.
- Livestock grazing in streams and riparian wetlands also has documented effects on the physical structure of wetlands.
- Irrigation can result in the creation and maintenance of wetlands in locations where they did not previously exist. This is a controversial regulatory issue in areas of the state that are irrigated.
- Conversely, agriculture can reduce the amount of water available to wetlands by either diverting water that would otherwise reach pre-existing wetlands, or imposing more efficient irrigation practices that reduce the amount of leakage reaching irrigation-related wetlands.
- Wetlands in tilled areas may experience greater water level fluctuations.
- Disruption of the soil through tilling and grazing can create a source of sediment than can be transported further downgradient. Sediments may also be carried by winds from tilled fields.
- Agricultural areas can have an increased load of nutrients and pesticides in surface runoff and groundwater.
- Agricultural practices in irrigated areas can lead to accumulation of salts in the upper soil horizons. Irrigation may leach out the accumulated salts.
- Fragmentation of wildlife habitat is a secondary consequence of loss of wetlands through agricultural practices. Clearing land for farming removes natural cover and connections between habitats.

3.4 Disturbances Caused by Urbanization

Urbanization creates disturbances that affect wetland functions, both at the scale of the watershed and within individual wetlands. These disturbances impose a variety of changes that profoundly affect watershed processes and, therefore, the downgradient drainage system and the wetlands found there. Changes include filling wetlands, clearing of vegetation, compaction of soil, modifications to water conveyance, alterations to riparian corridors, human intrusions, introduction of chemical contaminants, and increased areas of impervious surface.

A summary report by the U.S. Environmental Protection Agency (1993) concludes that urbanization strongly affects water movement within a watershed by increasing rates of surface flow, reducing subsurface volumes, and reducing baseflow. These pervasive, landscape-level changes commonly affect virtually all areas of an urban watershed (Dunne and Leopold 1978, Booth 1991, Booth and Reinelt 1993, Hollis and Thompson 1998).

Much of the scientific research on urbanization in the Pacific Northwest comes from the Puget Sound Wetlands and Stormwater Management Research Program initiated in 1986 in King County. Published results include theses by Azous (1991), Chin (1996), Ludwa (1994), and Taylor (1993). The book *Wetlands and Urbanization: Implications for the Future*, edited by Azous and Horner (2001), is a summary of the significant findings of the research. More information about the research done is available on the web site for the Center for Water and Watershed Studies at the University of Washington http://depts.washington.edu/cuwrm/ .

3.4.1 Loss of Wetlands Resulting from Urbanization

Approximately 13% of the wetland losses in the United States can be attributed to urbanization, road building, and other types of conversion (Tiner 1984). Kusler and Niering (1998) estimate that 85% of the wetlands in urban areas of the nation have been destroyed, and most of the remaining 15% are moderately to severely impaired in function. Data specific to Washington are very limited. One study (Bell 2002) found urban and residential development in King County accounted for 28% of the peat wetlands lost between 1958 and 2000.

The information available suggests that this trend will likely continue. It is estimated that more than 80% of the U.S. population will be living in urban areas by 2025, up from 74% in 1989 (Gerguson and Robinette 2001). Increases in urban population are generally accompanied by increased development density and sprawl. Wetlands in these areas are either converted to urban land uses or, if they are not directly disturbed, are degraded through a variety of causes as described in the following sections.

3.4.2 Increased Amount of Water in Wetlands Resulting from Urbanization

Urbanization is recognized as both increasing and decreasing the flows that reach downgradient aquatic systems such as wetlands. Greater volumes of water are generated more quickly while smaller, long-duration flows that would occur under less developed conditions are reduced or perhaps eliminated. Research has shown that collecting stormwater through modern storm drains, culverts, and catchments results in the rapid transport of large volumes of stormwater runoff into rivers, lakes, and wetlands at much faster rates and higher volumes than under predevelopment conditions (Dunne and Leopold 1978, Booth 1991, May 1996). Although some of the research has focused on the effects of urbanization on streams, the findings on changes in flow volumes, rates, and frequency apply equally to wetlands that receive storm drainage. Streams and wetlands are "intimately interconnected in the watersheds of western Washington" (Booth 1991).

Research conducted in the Puget Sound lowlands has shown statistically significant correlations between the effects of urbanization in a watershed and the hydrologic regime in that watershed (Konrad and Booth 2002). The amount of impervious surface within a contributing basin is a key influence on hydrologic patterns, and even small changes in watershed conditions have measurable influences on the flows and volumes of water in the system (Azous and Horner 2001).

3.4.2.1 Increased Frequency of Erosive Flows

One consequence of urbanization is an increase in the frequency of erosive flows within a watershed. As reported by Booth (1991), several studies concluded the most common effect of urbanization was an up to five-fold increase in peak flow rates from a given storm event. The largest relative increases in erosive flows were found for the smallest storm events. This is very significant because small storm events are the most frequently occurring storms. A small storm event is the *two-year-event*, a storm with a given volume of rain falling within a 24-hour period that has the statistical likelihood of occurring every two years (the statistics are based on over 40 years of measured rainfall). That means that small storm events have the greatest percent increase in flows over natural conditions, and frequent small storms have the greatest relative increase in erosive flows. Contrary to what might be expected, it is these recurring small storms that have the greatest cumulative effect on erosion and sedimentation, not the large, less frequent storm events (Booth 1991).

Thus, larger volumes of water enter channels and wetlands more rapidly after a given storm event in a basin where the removal of forests and the increase in impervious surfaces have altered hydrologic processes (Booth 1991). After an area has been developed and the forest canopy removed, high rates of flow continue for a longer duration. These flows may carry sediment and other pollutants into downgradient wetlands.

3.4.2.2 Increased Volume of Runoff and Longer Duration of Flows

Booth and Reinelt (1993) notes that a basin with increased imperviousness will experience an increase in the magnitude of runoff volume from a given storm event. The "typical" event occurs far more frequently. For example, the peak flows created from a two-year storm event, after urbanization, will occur far more frequently than every two years. Small storm events that did not create measurable peak discharges in forested conditions create measurable peak runoff flows in urbanized conditions, because the removal of the forest canopy makes the same size storm event result in far greater volumes of water reaching aquatic resources such as wetlands and streams. Modeling based on detailed data from basin monitoring identified that larger flows with more erosive force may occur in urbanized basins with much greater frequency, for example increasing from once or twice per decade to several times per year.

In urbanizing watersheds, stormwater ponds are designed to hold the excess volume of stormwater generated from the impervious surfaces. The ponds are designed to release stormwater at the same rate as that modeled for the natural vegetated basin for a given storm in pre-existing conditions (Booth 1991). However, in order for the ponds to discharge the increased volume of water at the same low rates, they must take more time, or cause an increased duration of flows.

3.4.2.3 Consequences of Changes in Water Regime

The consequences of the interplay between rates, volumes, and durations are complex. Research on the impacts of urbanization on stormwater and watershed processes indicates that urbanization results in several disturbances that can impact wetlands (Booth 1991, Azous and Horner 2001, Reinelt and Taylor 2001, Thom et al. 2001):

- Increased erosion
- Sediment movement and deposition
- Burying of vegetation
- Increased depths of inundation
- Water level fluctuations
- Downcutting of natural channels (which can remove riparian vegetation from the floodplain)
- Changes in the seasonal extent and duration of saturation and inundation
- Unstable substrates

Urbanization can also cause a decrease in interflow (shallow, subsurface flow) and base flow from the urbanized watershed (U.S. Environmental Protection Agency 1993). Changes in the volume of interflow may influence the hydroperiod of downgradient wetlands if they are fed by that shallow subsurface flow.

Roads and parking lots are an important component of the impervious surface area in a watershed. The City of Olympia in 1994 determined that transportation features (roads and parking lots) typically composed between 63% and 70% of total impervious area within suburban areas (Schueler and Holland 2000).

3.4.3 Increased Fluctuations of Water Levels Resulting from Urbanization

Reinelt and Taylor (2001) used water level fluctuation as the primary measure of wetland hydroperiod, stating: "Water level fluctuation is perhaps the best single indicator of wetland hydrology, because it integrates nearly all hydrologic factors." They documented four factors in a depressional wetland and its watershed that have the strongest influence on water level fluctuations:

- Forest cover in the watershed
- Impervious cover in the watershed
- Constriction of the wetland outlet
- Ratio of wetland to watershed area

Wetlands in basins with the highest degree of impervious area had the highest water level fluctuations. Wetlands in basins with 90% or more forested land cover and less than 3% impervious area generally exhibited smaller ranges in water level fluctuations (Reinelt and Taylor 2001). Further information on thresholds at which impervious surface influences aquatic resources is provided in Section 3.2.3.3.

Wetland size is also important in determining the effects of urbanization on water level fluctuations. Reinelt and Taylor (2001) observed that wetlands that were small in relation to their contributing watersheds had greater water level fluctuations and were dominated by surface inflow. Wetlands that were larger in comparison to their contributing watersheds had smaller water level fluctuations and more groundwater influence. Wetlands with a constricted outlet (undersized culvert, beaver dam, or embankment) had a greater water level fluctuation than wetlands with less constricted outlets.

Stormwater runoff from urbanization, as well as other land-use alterations, frequently causes several changes in how water levels fluctuate in wetlands. All aspects of fluctuations in water levels are changed by urbanization:

- The **magnitude** of the effect of storms is changed by causing a two-year event to act like a larger storm. A larger volume of water reaches the wetland more often. Urbanization can also prevent infiltration through native soils into the shallow groundwater zone (Booth 1991, Azous and Horner 2001).

- The **timing** of water's presence and duration is changed by the use of engineered stormwater systems. Water is collected from impervious surfaces into stormwater ponds. Infiltration into shallow groundwater is prevented. The stormwater is discharged at given rates for longer durations into downstream receiving waters (Booth 1991, Azous and Horner 2001).

- The **frequency** of runoff volumes from storm events increases. The volume of runoff normally generated from small storm events is generated by smaller volumes of precipitation (Booth 1991, Azous and Horner 2001, Reinelt and Taylor 2001, Thom et al. 2001).

- The **duration** of particular flows becomes extended as large volumes of stormwater are discharged at metered rates over longer periods of time (Booth 1991, Thom et al. 2001).

- The **rate of change** is increased through increasing the frequency and magnitude of water level fluctuations in urbanizing watersheds (Azous and Horner 2001, Reinelt and Taylor 2001, Thom et al. 2001).

3.4.4 Increased Input of Sediment Resulting from Urbanization

Researchers in the Puget Sound area have documented that urbanization increases erosion and this, in turn, increases the movement and deposition of sediment in depressional and riverine wetlands (Booth 1991, Azous and Horner 2001, Reinelt and Taylor 2001, Thom et al. 2001).

Studies at the national level undertaken by the U.S. Environmental Protection Agency confirm that sediment in urban runoff is a problem nationwide (Tasker and Driver 1988). Sediments and solids constitute the largest volume of pollutant loads to receiving waters in urban areas (U.S. Environmental Protection Agency 2003).

A major source of sediment in urban areas comes from construction when the surface of the soils is disturbed and exposed to erosive forces. Runoff from construction sites is by far the largest source of sediment in urban areas under development (U.S. Environmental Protection Agency 1993).

3.4.5 Increased Input of Nutrients Resulting from Urbanization

Research on the impacts of urbanization in the Puget Sound area (Booth 1991, Azous and Horner 2001, Reinelt and Taylor 2001, Thom et al. 2001) has also documented that urbanization increases the amount of nitrogen entering aquatic systems including wetlands. Studies at the national level undertaken by the U.S. Environmental Protection

Agency confirm that nitrogen in urban runoff is also a problem nationwide (Tasker and Driver 1988).

Nutrients are introduced into runoff from a number of different sources that include nutrients bound to sediment from construction sites, fertilizers applied to lawns, and decomposing grass clippings and leaves left on impervious surfaces (Johnson and Juengst 1997). Nutrients are also increased in groundwater in areas where wastewater is treated by septic systems (Valiela et al. 1993). More specifically, nutrients from septic systems have been correlated with an increase in nutrients in the groundwater that flows into lakes and their associated wetlands in urbanizing areas (Moore et al. 2003).

In addition to the application of fertilizers in residential areas, nitrogen is introduced into aquatic systems and wetlands from the release of nitrogen compounds in car and truck engines and through the burning of wood and coal (Paerl and Whitall 1999). The amount of nitrogen coming from the deposition of these air pollutants in the United States is about 20% of the total excess nitrogen derived from human activities (Prospero et al. 1996). In heavily urbanized areas such as the Eastern Seaboard, the total amount of nitrogen coming from combustion can be as high as 40% or more of the total input by all human activities (Valigura et al. 1996).

3.4.6 Increased Input of Toxic Contaminants Resulting from Urbanization

In addition to sediment and nutrients, urban land uses generate a wide range of pollutants that include the following (U.S. Environmental Protection Agency 1993):

- Heavy metals (copper, lead, zinc)
- Hydrocarbons
- Organic matter that reduces oxygen
- Pesticides

Schueller and Holland (2000) cite a number of studies indicating that urban pollutant loads are directly related to the amount of impervious surface in the watershed. Impervious surfaces such as roads, parking lots, and storage yards are places where toxics from numerous sources collect. Precipitation falling on the impervious surfaces washes the collected chemicals and particles into the storm drain system (Schueller and Holland 2000).

The runoff from many different types of land use in urban areas can be toxic to aquatic life. Pitt et al. (1995) studied the relative toxicity of the runoff from different types of land uses in urban and suburban areas. Parking areas, storage areas, and landscaped areas (lawns, gardens) had the highest toxicity with approximately 20% of the samples being highly toxic. Over half of the samples of runoff from these urban land uses were moderately toxic.

Sriyaraj and Shutes (2001), working in London, documented that hard rains after extended dry periods result in the greatest concentrations of pollutants. This is also known to occur in Washington, where the greatest concentration of pollutants in surface runoff is typically observed in the fall with the first rains following summer drought (Booth 1991).

3.4.6.1 Heavy Metals and Hydrocarbons

Most heavy metals in urban runoff are adsorbed to sediment particles, although copper and zinc can occur in dissolved forms (Canning as referenced in Newton 1989). The sources of heavy metals are various including motor vehicle brake linings, tire particles on roadways, emissions from vehicles, and industrial sources.

Sriyaraj and Shutes (2001) found that sediment from road runoff had high to moderate levels of heavy metals associated with it, and the metals were deposited within the sediments of the receiving wetland. Heavy metals, such as lead, zinc, copper, and cadmium, are some of the pollutants that accumulate on roads during dry summers. These pollutants are particularly concentrated when they are washed off during intense storms following long dry periods (Sriyaraj and Shutes 2001). Thurston (1999) found that lead and petroleum hydrocarbons were the most common pollutants attached to particles in an urban wetland receiving direct runoff from a municipal garage parking lot.

Most of the adsorbed metals are buried in sediment deposits within wetland substrates, thereby becoming substantially "locked up" from further biological activity (Canning as referenced in Newton 1989) when covered by un-contaminated sediment. Where contaminated sediments are constantly being discharged to wetlands (e.g., urban stormwater discharges), however, new contaminated sediments are constantly coming in. Thus, there is always contamination in the biologically active zone. Also, if the pH of the incoming water changes some toxic metals may be released (see Section 2.6.1.4).

3.4.6.2 Organic Matter

Another contaminant present in runoff from urban areas is organic matter (examples listed below). As this organic matter decomposes in the water, it uses up oxygen that is dissolved in the water (called dissolved oxygen or DO). DO plays the same role as atmospheric oxygen in that it is critical for biological activity in aquatic communities. Oxygen is used by aquatic organisms. It is also used by bacteria for the decay of organic matter. This is called the biological oxygen demand (BOD) of the system. In natural systems, BOD fluctuates as oxygen use and organic inputs vary both daily and seasonally. The natural BOD of a system is thrown out of balance when there is excessive organic matter in the system. An increased BOD results in a decreased availability of dissolved oxygen.

Contaminants in urban runoff that cause increases in BOD include:

- Septic system effluent
- Oil and grease
- Organic matter such as dog and cat feces
- Incidental sources from atmospheric fallout

Direct urban runoff can create a demand for oxygen that is equal to or greater than that from sewage effluent. BOD from urban runoff can have substantial cumulative effects (Canning as referenced in Newton 1989).

3.4.6.3 Pesticides

Pesticides in urban areas are used for residential and commercial landscaping. According to studies conducted in the Puget Sound Basin, more types of pesticides were detected in urban streams than in agricultural streams (Bortleson and Davis 1997). Furthermore, more pounds of pesticides were applied in urban areas than in agricultural areas (Tetra Tech 1988 as reported in Voss et al. 1999). Voss et al. (1999) found 23 pesticides in urban streams in King County of which five exceeded the recommended maximum concentrations set by the National Academy of Science. Although all these data were collected from streams it can be assumed that riverine wetlands that intersect these urban streams can be subject to these pesticides as well.

3.4.7 Fragmentation of Habitat Resulting from Urbanization

Urbanization causes fragmentation of habitat as new developments divide undisturbed areas (COST-Transport 2003). Conversion of the land for urbanization has turned large, continuous patches of habitat into numerous small patches, which are isolated from each other and surrounded by land uses that are not hospitable to many native wildlife species (Aurambout 2003). The fragmentation of habitat continues to increase as the human population grows (Dale et al. 2000). Developed lands in the U.S. increased by 18% between 1990 and 2000 to total 4.4% of the area of the country (Dale et al. 2000).

Wetlands, as part of an undisturbed landscape, are also subject to the fragmentation that results from urbanization. Gibbs (2000) analyzed the distribution of wetlands along urban to rural gradients in New York State and in Maine and found statistically significant correlations between the density of human population and two measures of fragmentation – the average distance between wetlands and the percent of the landscape that was in wetlands.

3.4.8 Other Disturbances Resulting from Urbanization

Several other types of disturbances have been attributed to human activities in urbanizing areas:

- Alteration of soils
- Construction of roads
- Noise
- Recreational access
- Invasion by exotic plant and animal species, including household pets

These disturbances are not discussed in detail in this chapter because little information in the literature was found quantifying how urbanization creates these disturbances. The impacts of these disturbances on wetlands have been documented and are summarized in Chapter 4.

3.4.9 Summary of Key Points

- Increases in urban population are generally accompanied by increased development density and sprawl. Wetlands in these areas may be converted to urban land uses or may be degraded through a variety of causes.
- Urbanization results in modifications to water movement, alterations to riparian corridors, human intrusions, introduction of chemical contaminants, and increased areas of impervious surface. These changes profoundly affect environmental processes in contributing basins and, therefore, the downgradient drainage systems.
- Urbanization alters the movement of water into aquatic systems. Consequences of increased amounts of water include an increased frequency of erosive flows, greater volume of runoff, and longer duration of high flows.
- With urbanization comes increased transport of sediment, nutrients, metals, oil, pesticides, and other contaminants in surface runoff.
- Fragmentation of habitat results as the total area of wetlands is reduced and the connections between wetlands and other habitats are eliminated.

3.5 Disturbances Caused by Forest Practices

In general, forest practices cause several types of disturbance that can impact the factors that control wetland functions and therefore affect the performance of those functions. These disturbances include (as reviewed in Cooke in press):

- Increased peak flows
- Increased water level fluctuations
- Increased nutrients
- Increased sedimentation
- Changes in soils
- Invasion by exotic species

The effects of forest practices have recently received much attention. As a result, the scientific literature is being reviewed and synthesized by the Washington State Department of Natural Resources and is now in a draft form (Cooke in press). Therefore, this review of the literature does not cover the disturbances that result from forest practices and their impact on wetland functions.

3.6 Disturbances Caused by Mining

Surface mining generates large quantities of unusable rock that is often left on the surface after it is extracted. This exposes the rock (called spoils) to an oxidizing environment, resulting in a complex series of chemical reactions. The minerals contained in the spoils are not in equilibrium with the oxidizing environment and almost immediately begin weathering and mineral transformations.

The reactions are analogous to "geologic weathering" which takes place over extended periods of time (hundreds to thousands of years) but the rates of reaction are orders of magnitude greater than in "natural" weathering systems. The accelerated reaction rates can release damaging quantities of acidity, metals, and other soluble components into the environment (U.S. Department of the Interior, Office of Surface Mining 2003).

Thus, the two major disturbances created by surface mining are (Adamus et al. 2001):

- An increase in the levels of heavy metals that are toxic to many organisms
- An increase in the acidity of surface waters

Another type of mining activity that occurs in the state is gravel mining in streams and floodplains. We were unable to find any published information on the impacts of gravel mining on wetlands, and research into this question is only beginning at the national level by the U.S. Geological Survey (Spooner 2004). As a result, we were unable to synthesize the information on the impacts of this activity.

3.7 Chapter Summary and Conclusions

The focus of Chapter 3 has been to describe how different land uses may change the environmental factors that control wetland functions. A general conclusion that can be

made from the scientific literature is that disturbances of environmental factors can occur at several geographic scales. Much of the early research focused on disturbances that occur at a single site or wetland. More recent research has documented the significance of disturbances that occur at the much larger scale of a watershed (called the landscape scale). The disturbances created by different land uses are summarized in Table 3-3 (at the end of this section) by the type of land use, the severity of the disturbance, and the scale at which the disturbance occurs. This table represents a synthesis of the severity of impacts by the authors of this document based on the information in the literature.

The effects of different land uses on the flow and fluctuations of water are well documented. Changes in land uses and vegetation communities on the land, whether for agriculture or as a result of urbanization, alter the patterns of surface and shallow groundwater movement across a landscape. Flows of water can be reduced or increased by different land uses as can the frequency and amplitude of water levels.

Removal of vegetation and/or compaction of native soils through agricultural practices, creation of lawns or grazed pastures, or creation of impervious surfaces all have the same relative consequence: increased volumes of water and rates of flows after a given storm event. The threshold of roughly 10% imperviousness within a basin appears to be the point above which significant impacts begin to occur to aquatic resources based on research in the Puget Sound Basin.

While the effects of urbanization on water movement have been extensively studied, agriculture can also influence the water regime of wetlands, leading to loss of wetlands in some areas and creation or maintenance of wetlands in other areas where wetlands did not originally exist, such as areas influenced by irrigation.

Human activities also increase sediment and other pollutants in runoff. In agricultural areas, pesticides and fertilizers can contribute to contamination of surface waters. In urban areas, stormwater runoff frequently contains sediment, organic matter, phosphorus, metals, and other pollutants. Pollutants often adhere to sediment particles that enter wetlands. Mining increases the acidity of surface waters as well as adding toxic heavy metals. Logging increases sediments in a watershed and can also change the amount of water and its fluctuations.

Fragmentation of habitats is of increasing concern. As connections between wetlands and other habitats are broken and more wetlands across the landscape are converted to other uses, the remaining habitat becomes more isolated.

A key finding of this chapter is that different land uses may cause the same change in the controls of wetland functions. For example, urban land uses, agricultural practices, and logging have all been shown to increase sediments in a watershed. From the wetland's "point of view," the source of the sediment is irrelevant—the impact of excess sediments on wetland functions is similar, regardless of the source of sediments.

Chapter 4 shifts from a focus on the disturbances caused by human land uses (agriculture, urbanization, logging, and mining) to describe how these disturbances impact wetlands and their functions.

Table 3-3. Disturbances resulting from different land-use practices that can change the factors that control wetland functions.

Disturbance	Scale of Disturbance	Agriculture	Urbanization	Mining
Changing the physical structure within wetlands (filling, vegetation removal, tilling of soils, compaction of soils)	Site scale	xx	xx	h
Changing the amounts of water	Landscape scale	xx	xx	?
	Site scale	xx	xx	h
Changing fluctuations of water levels (frequency, amplitude, direction of flows)	Landscape scale	xx	xx	?
	Site scale	xx	xx	h
Changing the amounts of sediment	Landscape scale	xx	xx	h
	Site scale	xx	xx	h
Increasing the amount of nutrients	Landscape scale	xx	xx	nm
	Site scale	xx	xx	nm
Increasing the amount of toxic contaminants	Landscape scale	xx	xx	x
	Site scale	xx	xx	xx
Changing the acidity	Landscape scale	nm	nm	x
	Site scale	nm	nm	xx
Increasing the concentrations of salt	Landscape scale	x	nm	nm
	Site scale	x	nm	nm
Fragmentation	Landscape scale	xx	xx	h
Other disturbances	Site scale	xx	xx	h

Key to symbols used in table:
(xx) land use creates a major disturbance of environmental factors that affects large areas in the state
(x) land use creates a disturbance
(nm) studies on impacts of this land use do not mention this disturbance
(h) literature is lacking but disturbances can be hypothesized based on authors' experience
(?) information lacking

Chapter 4

Negative Impacts of Human Disturbances on the Functions of Wetlands

4.1 Reader's Guide to This Chapter

Chapter 4 integrates the concepts discussed in Chapter 2 and Chapter 3. Chapter 2 described the functions performed by wetlands and the environmental factors that control functions of wetlands. Chapter 3 discussed the major disturbances to the environment caused by different human activities and uses of the land. This chapter continues by summarizing how each of the disturbances ultimately leads to impacts to wetland functions.

As mentioned in Chapter 3, disturbances to wetlands can alter how they function. Changes that are caused by human disturbances are often called *impacts* to separate them from changes that are caused by "natural" or non-human disturbances. From a legal perspective (National Environmental Protection Act), human impacts are divided into *direct impacts*, those which are caused by the action and occur at the same time and place, and *indirect impacts*. Indirect impacts are caused by an action but occur later in time or are farther removed in distance, but are still reasonably foreseeable. (http://ceq.eh.doe.gov/nepa/regs/ceq/1508.htm#1508.1)

Impacts can be either beneficial or detrimental to the ecosystem, environmental process, or species. Defining an impact as either beneficial or detrimental depends on the values of the society or group making the decision (Beanlands and Duinker 1983). The natural system does not judge a change as either good or bad; it is we, as a society, that make that judgment. Social values, as represented by its laws, provide the means of determining the importance of human impacts (Beanlands and Duinker 1983).

The Growth Management Act and the state and federal clean water acts all have the protection of wetland functions and values as a goal. Thus, human impacts to wetlands, from this perspective, need to be considered in terms of those that reduce the level of functions they perform or the values they represent.

Therefore, the objective of the synthesis in this chapter is to summarize the information on the changes caused by human disturbances that reduce the level of different functions performed by wetlands. For this reason the chapter is titled *negative impacts*. When the word *impact* is used it assumes there is a reduction in the levels of functions and the societal values they represent.

4.1.1 Chapter Contents

Major sections of this chapter and the topics they cover include:

Section 4.2, The Geographic Scale of Impacts to Wetland Functions describes how disturbances that impact functions of wetlands can occur either within the wetland itself or in the surrounding landscape. While the literature generally does not distinguish the scale of the disturbance when assessing impacts on wetland functions, there are some disturbances at the site scale that can remove all or most functions of the wetland (such as changing the physical structure of the wetland through filling).

Following this introduction, the chapter continues by describing how the major types of disturbances resulting from human activities affect wetland functions. As discussed in Chapter 3, different land uses may create the same type of disturbance (for example, both agriculture and urbanization may cause sedimentation). Therefore, each of the remaining sections of this chapter focuses on the different types of disturbances, without division by land-use type, and their impact on each wetland function. The following is a list of the disturbances discussed in this chapter:

Section 4.3, Impacts from Changing the Physical Structure within a Wetland

Section 4.4, Impacts from Changing the Amount of Water in a Wetland

Section 4.5, Impacts from Changing the Fluctuation of Water Levels within a Wetland

Section 4.6, Impacts from Changing the Amounts of Sediment Coming into a Wetland

Section 4.7, Impacts from Increasing the Amounts of Nutrients Coming into a Wetland

Section 4.8, Impacts from Introducing Toxic Contaminants to a Wetland

Section 4.9, Impacts from Changing the Acidity (pH) of Soils or Water in a Wetland

Section 4.10, Impacts from Increasing the Concentrations of Salt in a Wetland

Section 4.11, Impacts from Fragmenting Wetland Habitats

Section 4.12, Impacts from Other Human Disturbances on Wetlands

Within each section, the impact of each disturbance is summarized in terms of the following wetland functions:

- Impacts on hydrologic functions
- Impacts on functions that improve water quality
- Impacts on plants
- Impacts on invertebrates
- Impacts on amphibians and reptiles

- Impacts on fish
- Impacts on birds (species closely associated with wetlands)
- Impacts on mammals (species closely associated with wetlands)

Section 4.13, Chapter Summary and Conclusions ties together the major concepts presented in the chapter.

4.1.2 Where to Find Summary Information and Conclusions

Each major section of this chapter concludes with a brief summary of the key points resulting from the literature on that topic in a bullet list format. The reader is encouraged to remember that a review of the entire section preceding the summary is necessary for an in-depth understanding of the topic.

For summaries of the information presented in this chapter, see the following sections:

- Section 4.3.9
- Section 4.4.9
- Section 4.5.9
- Section 4.6.9
- Section 4.7.9
- Section 4.8.9
- Section 4.9.9
- Section 4.10.9
- Section 4.11.9
- Section 4.12.6

In addition, Section 4.13 provides a summary and conclusions about the overarching themes gleaned from the literature and presented in this chapter.

4.1.3 Sources and Gaps in Information

Data on some of the subjects related to the negative impacts of human disturbances on wetland functions are abundant for select areas in the state. For example, the Puget Sound Wetlands and Stormwater Management Research Program (summarized in Azous and Horner 2001) has provided several studies on how changes in land uses in a watershed affect the physical, chemical, and biological processes in wetlands of the Puget Sound lowlands. The impacts on wetlands in other areas of the state are less well studied.

Similarly, studies on the effects of changes in wildlife habitat resulting from physical changes within wetlands and fragmentation between habitats have been performed in Washington for some species and some types of habitat changes. The impacts to other species are less well studied or have only been examined in other states or other countries. Information from other locales is included for these topics when relevant.

This chapter contains text that was adapted (re-organized and paraphrased) from a review of current scientific literature on the impacts of human activities on wetlands and their functions undertaken by the U.S. Environmental Protection Agency (Adamus et al. 2001). This review represents a very detailed summary of the literature published between 1990 and 2000 regarding wetlands across the United States. Portions of the review that were considered relevant to wetlands in Washington State were adapted for inclusion in this chapter, with permission from Dr. Adamus. The sections of this chapter that incorporate text adapted from the Adamus et al. (2001) review include:

- **Sections 4.3.3 – 4.3.8**, the impacts on plants, and habitat for invertebrates, reptiles and amphibians, fish, and mammals from changing the physical structure in the wetland
- **Sections 4.4.3 – 4.4.7**, the impacts on plants, invertebrates, amphibians and reptiles, fish, and birds from changing the amount of water in the wetland habitat
- **Section 4.5.4**, the impacts on invertebrates from changing the fluctuations of water levels in the wetland habitat
- **Sections 4.6.3 – 4.6.4**, the impacts on plants and invertebrates from changing the amounts of sediment in the wetland habitat
- **Sections 4.7.3, 4.7.4, 4.7.7**, the impacts on plants, invertebrates, and birds from increasing the amount of nutrients in the wetland habitat;
- **Sections 4.8.3 – 4.8.7**, the impacts on plants, invertebrates, amphibians and reptiles, fish, and birds from increasing the amount of toxic contaminants in the wetland habitat;
- **Section 4.9.3 – 4.9.7**, the impacts on plants, invertebrates, amphibians and reptiles, and birds from changing the acidity in the wetland habitat;
- **Sections 4.10.4, 4.10.7**, the impacts on invertebrates and birds from increasing the concentration of salts in the wetland habitat;
- **Section 4.12.1, 4.12.5.4**, the impacts on plant communities from altering soils and the impacts of exotic invertebrates on native invertebrates in wetlands.

The literature sources cited in the portions of the text that were adapted from the report by Adamus et al. (2001) are included in the list of references at the end of Volume 1. These sources, however, were not obtained and reviewed independently.

4.2 The Geographic Scale of Impacts to Wetland Functions

The disturbances that impact functions in wetlands can occur either within the wetland itself or in the surrounding landscape. Chapter 2 introduced the idea that the controls of wetland functions occur at both the "site scale" and the broader "landscape scale." As with the controls of wetland functions, disturbances caused by human activities can also occur at the same two scales (site and landscape).

For example, increased nutrients can flow into a wetland directly from an adjacent lawn or from animals grazing within the wetland (disturbance at the site scale). The nutrients could also originate from development or fertilized fields somewhere higher in the contributing basin (disturbance at the landscape scale). As another example, the water levels in a wetland can be increased through the direct discharge of stormwater into a wetland (the site scale) or by adding impervious surface higher in the contributing basin (the landscape scale).

Much of the discussion in this chapter does not differentiate the scales at which the disturbance occurs. For example, the impacts on wetland functions resulting from excess nutrients or higher water levels can be expected to be the same whether they are delivered directly to the wetland or come from a distant source in the contributing basin. The literature does not usually differentiate between scales when discussing the impacts on wetland functions.

However, an alteration to the physical structure of the wetland itself is a type of disturbance that occurs only at the site scale. Filling, removing vegetation, tilling, or grazing within a wetland has a direct impact on the functions at that site. The most extreme impact to a wetland is the complete removal of all the factors that contribute to the existence of the wetland. Thus, filling a wetland or draining all the water eliminates all of the wetland functions because the wetland no longer exists.

4.3 Impacts from Changing the Physical Structure within a Wetland

Disturbances that directly change the structure of wetlands can be so severe that the wetland is destroyed. Filling or draining a wetland can so alter the water regime that the land can no longer support the wetland vegetation and maintain hydric soils. If a wetland is lost, most if not all of its wetland functions are also lost. Dahl (1990) estimated that 31% of the wetlands in Washington State had been lost prior to the 1980s as a result of filling or draining to the extent there is no longer enough water to maintain areas as wetland.

There are, however, some human alterations of the structure in wetlands that do not result in the complete loss of functions, including:

- Human removal of vegetation (e.g., logging, mowing, or application of herbicides)
- Animal grazing
- Alteration of the soil through tilling or compaction
- Partial draining

This section describes what the literature reports about how these alterations impact wetland functions. The impacts of grazing and removal of vegetation are better understood than those of alterations to the soils. Information was not available on how some of these alterations affect wetland functions described in the following sections, and some impacts are hypothesized based on synthesizing other information.

4.3.1 Impacts on Hydrologic Functions from Changing the Physical Structure

No information was found on how changing the physical structure of wetlands impacts their hydrologic functions (reducing peak flows, reducing erosion, and recharging groundwater). One could hypothesize that removing erect and persistent vegetation (emergent, shrub, or forest species) may impact the reductions in water velocity that occur in wetlands. The density of vegetation is a factor in reducing water velocity during flooding or storm flows (Adamus et al. 2001). If this vegetation is removed, the wetland will probably not be as effective at slowing these flows (in other words, there will be a change in how this wetland function is performed). As a result, downstream erosion and flooding may increase.

4.3.2 Impacts on Functions that Improve Water Quality from Changing the Physical Structure

No information was found on how changing the physical structure of wetlands affects how well wetlands remove pollutants. Removal of vegetation has impacts on both bacteria and plants, and this may affect the uptake and transformation of nutrients and toxic compounds in a wetland. The same can be hypothesized for direct alteration of soils, which may affect the chemical properties in a wetland. It is not possible, however, to predict or hypothesize how such changes might alter the wetland functions (that is, whether functions to improve water quality will increase or decrease).

4.3.3 Impacts on Plants from Changing the Physical Structure in a Wetland

Plants are one of the major factors that determine the physical structure within a wetland. Thus, changing the physical structure in a wetland means that the plants, and the structure they provide, have been removed or modified. Examples of structure that is based on plants include different layers within a forest (e.g., canopy, sub-canopy, ground cover) or the sub-surface root mass of perennial plants. In addition, removal of any vegetation causes at least a short-term change in plant biomass and possibly a change in the composition of plant species.

Vegetation can be removed by fire, tilling, mowing, or grazing (Newman 1991, Naiman and Rodgers 1997). Mortality from logging, dredging or construction activities, flooding, as well as contaminants such as herbicides can also cause loss of plants (Adamus et al. 2001). The process by which vegetation is removed or damaged appears to influence the type, duration, and magnitude of the impact on plants. Vegetation patterns in some wetlands result in part from the differing causes of plant removal and whether those causes are lethal or not (Heitschmidt and Stuth 1991, Baldwin and Mendelssohn 1998).

Impacts to the population of plants in a wetland also depend partly on the process through which the plants re-establish. When all or nearly all of the plants are removed through methods lethal to vegetation (such as with herbicides), recovery occurs mainly via recruitment of seeds. When removal is by non-lethal methods (such as grazing), recovery often is by re-growth of the plants.

The effects of grazing on plants and other aspects of ecosystems has received much attention in the last three decades because of the potential impacts in semi-arid areas (see review in National Research Council 1984). Impacts on wetlands have been studied less intensively, but some information is available. The impacts of grazing on wetland plants depend partly on the density of grazers, how long, and when they are present in the grazed area, the availability of food and water in nearby alternative habitats, and the season (Clary 1995, Fitch and Adams 1998). Specifically:

- In a laboratory experiment Crossle and Brock (2002) found that simulations of grazing changes the reproductive output of plants in wetlands in different ways and that this can change the populations by changing the proportions of seed produced.
- A study of riparian vegetation in eastern Oregon used different simulated grazing treatments to determine the effects of light and heavy grazing (Clary et al. 1996). While not clearly identified, it is evident that some of the plots were in riparian wetlands and others in non-wetland riparian habitats. The authors observed that herbaceous plants increased in growth and vigor in the ungrazed and moderately grazed plots, particularly if the grazing occurred only in the spring. Heavier grazing that lasted all season had detrimental effects on the vegetation.
- In another study in Oregon of riparian meadows, Clary (1995) found that the biomass of the grass redtop (*Agrostis* sp.) remained stable or increased at a low-elevation site

the year following simulated grazing treatments. At higher elevations, sedge species (almost all of which are found mostly in wetlands) either maintained or declined in biomass production the following year. The author concludes that grazing only annually (for several months once a year as opposed to year-round) would significantly reduce sedge production, while not decreasing redtop production.

4.3.4 Impacts on Invertebrates from Changing the Physical Structure of the Habitat

The presence of invertebrate species in a wetland is influenced by the type of plants that grow there. For example, in a Washington pond, some leeches (*Helobdella*), aquatic sowbugs (*Asellus*), mayflies, and some dragonflies (especially the large-bodied *Anax*) were more commonly associated with emergent vegetation than with submerged vegetation or open water areas. Midges, freshwater shrimp (*Hyalella azteca*), and mollusks (especially *Lymnaea* sp., *Gyraulus* sp., and *Anodonta* sp.) were more common on the submerged plants (Parsons and Matthews 1995).

The removal of vegetation either mechanically or through grazing, therefore, has a significant impact on the presence and abundance of invertebrate species in a wetland. Wetland managers often manipulate the structure of vegetation by mowing, burning, plowing, or planting to encourage or discourage populations of desirable or undesirable invertebrates (Batzer and Resh 1992, Kirkman and Sharitz 1994, de Szalay et al. 1996, de Szalay and Resh 1997).

Adamus et al. (2001) conclude from their literature review that the removal of vegetation:

- Removes substrates that would otherwise provide additional vertical space in the water column for invertebrates to colonize
- Removes shade, thus increasing water temperature and causing stress for invertebrates
- Increases the circulation and perhaps the velocity of water, with accompanying increases in dissolved oxygen and possible resuspension of sediments; this may result in changes to the habitats that favor different species of invertebrates
- Reduces inputs of leaf litter that provide food to some invertebrate taxa
- Reduces structures that otherwise shelter invertebrates from predators (Jordan et al. 1994)

Complete removal of vegetation generally reduces the richness of the wetland invertebrate community, but patchy removal or moderate grazing sometimes increases richness (McLaughlin and Harris 1990, Gray et al. 1999).

4.3.5 Impacts on Amphibians and Reptiles of Changing the Physical Structure of the Habitat

The information on the impacts of direct disturbances to the physical structure of a wetland on amphibians is ambiguous for Washington and the impacts cannot be predicted. In the Puget Sound Basin of Washington, surveys of 19 wetlands found no correlations that were statistically significant between amphibian richness and vegetation form (i.e., structure of plants) (Richter and Azous 1995). Plant stem diameter is apparently more important than plant species (Richter 1997).

Removing dense emergent vegetation, however, may impact populations of amphibians. A survey of 40 wetlands in the Puget Sound area found more native species of amphibians among wetlands containing dense emergent vegetation (Adams et al. 1998). Dense vegetation may help protect the larvae of native aquatic amphibians from larger predators. It can be hypothesized, therefore, that removing dense emergent vegetation would probably impact the populations of amphibians.

Other studies have focused on the impacts of grazing. Based on personal observations, Maxell (2000) asserts that livestock grazing can impact amphibians through:

- Trampling of vegetation that results in loss of habitat and reduces insect populations that are food sources for amphibians
- Changes in substrate composition and bank structure
- Increased sedimentation

These observations have been confirmed by Knutson et al. (2004) who reported a statistically significant negative effect of grazing and direct access of livestock to ponds on the reproduction of amphibians.

However, a study of the Columbia spotted frog in 127 ponds in northeastern Oregon does not support these findings. Bull and Hayes (2000) found no significant differences between grazed and ungrazed ponds in terms of the numbers of frog egg masses and the abundance of recently metamorphosed frogs. The volume of egg masses was larger at grazed sites, possibly due to a greater presence of adults or an older population (older, larger females lay bigger egg masses). Six of the eight most productive ponds (those with 20 or more egg masses) were grazed, indicating that grazing had no detrimental effect on this frog in these wetlands.

The differences in the conclusions between these studies may be a result of different intensities of grazing in the wetland. Jansen and Healy (2003) found a clear relationship (statistically significant) between the condition of a grazed wetland (as measured by vegetation and water quality) and the species richness of frogs. They also found a direct correlation between the intensity of grazing and the condition of a wetland.

4.3.6 Impacts on Fish from Changing the Physical Structure of the Habitat

Information in the literature did not differentiate between the responses of resident and anadromous fish to changes in the physical structure in wetlands. The information available addresses impacts to fish in general. For example, the removal of vegetation can have a significant impact on the fish present in a wetland as a result of (Adamus et al. 2001):

- Increased water temperature that may go above the tolerance limits of certain species
- Decreased cover and thereby increased susceptibility to predation
- Changes in foods and their availability

Woody material is especially important as a source of cover for fish in off-channel wetlands such as oxbows and sloughs and in lakes (Leitman et al. 1991, Dewey and Jennings 1992, Fausch and Northcote 1992, McIntosh et al. 1994).

In wetlands along the fringes of lakes, submerged plants are particularly important and their removal can change the habitat for fish. For example, declines in plants resulting from introductions of grass carp (Bain 1993) have been linked to an increase in the proportion of fish species found in limnetic areas (open water) (Bettoli et al. 1991, Maceina et al. 1991, Martin et al. 1992). However, intentional thinning of plant beds can sometimes result in higher growth rates of some age classes of lake fish, presumably by giving them better access to invertebrates that are their food source (Olson et al. 1998).

One impact that has been hypothesized in situations where the physical structure of wetlands is changed is the "stranding of fish (R. Friesz, K. March, B. Zeigler, Washington State Department of Fish and Wildlife, personal communications 2000-2004). Changing the shape or drainage of wetlands can create situations where shallow surface water is connected to streams such as during flood events or high precipitation and then isolated as water levels drop. This may result in the stranding of fish in these shallow pools, and their subsequent demise as the temperatures rise and oxygen levels decrease.

4.3.7 Impacts on Birds of Changing the Physical Structure of the Habitat

Many guilds of birds are sensitive to the presence and type of vegetation and its location in relationship to open water (Kauffman et al. 2001). The removal of vegetation can, therefore, be expected to change the distribution and abundance of birds in wetlands. For example, the rearing success of waterfowl in wetlands is reduced by removing herbaceous cover because it exposes the young to predation (Skovlin 1984).

Grazing has also been found to change the distribution of birds. In a study in southeastern Oregon on the effects of grazing on birds, researchers used exclosures to remove livestock from portions of riparian meadows (Dobkin et al. 1998). They found that the richness and abundance of bird species increased within the exclosures in comparison to the plots that

remained available for livestock grazing. Moreover, the exclosures were dominated by wetland-associated birds while the open plots were dominated by upland bird species.

The changes in physical structure of wetlands that result from grazing can have both positive and negative impacts on shorebirds that use freshwater wetlands (Buchanan, 2004). The negative impacts he reported include the direct trampling that destroyed eggs and nests, the compacting of soil that reduce populations of invertebrate prey, and an increased erosion that reduced populations of invertebrate prey in semi-arid regions.

The changes in the structure of vegetation that result from the conversion of forested wetlands to emergent and open water wetlands can alter species composition and richness of breeding birds. For example, 53% of the bird species that formerly used forested wetlands no longer occur regularly where such forests have been logged and converted to emergent wetlands (Doherty 2000 as reported in Adamus et al. 2001). In the Columbia Basin, where forests are not present, changes in the vegetation of the buffer also had impacts. Heavy grazing next to wetlands removed buffer vegetation and reduced waterfowl production by 50% (Foster et al. 1984).

4.3.8 Impacts on Mammals from Changing the Physical Structure of the Habitat

Many mammals are sensitive to the presence and type of vegetation and its location in relationship to open water. The removal of vegetation is therefore expected to change the distribution and abundance of mammals in wetlands (Adamus and Brandt 1990).

Adamus and Brandt (1990) created a synthesis of the literature on mammal habitat which serves as the basis for the following discussion.

The species richness of small mammals in wetlands has been correlated with the complexity of vegetation structure (Arner et al. 1976, Searls 1974, Landin 1985, Nordquist and Birney 1980, Stockwell 1985, Simons 1985). Removal of vegetation and associated long-term destruction of den sites in both wooded and emergent wetlands have caused changes in furbearer populations and small-mammal communities (Krapu et al. 1970, Malecki and Sullivan 1987). In contrast, restoration of riparian vegetation has led to increases in use by mink (Burgess and Bider 1980).

Grazing at levels recommended by the Natural Resources Conservation Service had no significant effect on the abundance or distribution patterns of small mammals in a cottonwood floodplain in Colorado (Samson et al. 1988). Based on this study, controlled grazing that does not contribute to structural changes in vegetation, appears to have no significant effect on the abundance and distribution of small mammals.

4.3.9 Summary of Key Points

- Filling or draining a wetland can so alter the water regime that the land can no longer support wetland vegetation and maintain hydric soils. If a wetland is lost, most if not all of its functions are also lost.
- Some direct disturbances of wetlands, such as removal of vegetation, grazing, and alteration of the soil, change the wetland functions but do not result in the complete loss of functions.
- Impacts of removing vegetation on the habitat functions in wetlands have been documented for invertebrates, fish, birds, and mammals. Impacts on amphibians, however, are ambiguous. Impacts to the hydrologic and water quality functions resulting from vegetation removal can only be hypothesized since no information was found in the literature.
- Impacts of grazing on habitat functions have been documented for invertebrates and birds and are somewhat conflicting for amphibians. The one study of mammals suggests that low levels of grazing in a floodplain may have minimal impacts on the habitat of this group. No information was found on impacts of grazing on the hydrologic and water quality functions.
- No information was found on the impacts of soil alterations (through tilling and compaction) on any of the functions performed by wetlands.

4.4 Impacts from Changing the Amount of Water in a Wetland

The quantity of water in the landscape is a critical factor in controlling how wetlands function. Many human land uses change the amount of water flowing into and out of wetlands, thereby creating a disturbance that affects the performance of functions in wetlands. The literature is quite clear that the frequency, timing, and duration of water in the landscape determine the presence of a wetland and the functions that it provides (see Chapter 2). How water enters a wetland, how long it is present, and the depths to which it is impounded all influence the functions that a wetland can provide or perform (Brinson 1993b, Mitsch and Gosselink 2000).

The movement and routing of water above and below the surface is the primary force in transporting nutrients, sediment, salts, and contaminants, and this in turn affects the functions provided by wetlands (Naiman et al. 1992). Water moves (or carries) sediment, nutrients, and energy throughout a watershed (Naiman et al. 1992). Changes in the amount of water and thereby the depth of inundation in a wetland, can alter how sediments, nutrients, and toxic contaminants come into a wetland and how they are “processed” within the wetland.

4.4.1 Impacts on Hydrologic Functions from Changing the Amount of Water

Specific documentation was lacking on how increasing or decreasing amounts of water may affect wetland functions in reducing flooding or erosion or recharging groundwater. It can be hypothesized, however, that the storage capacity of a wetland in a depression that drains to areas prone to flooding will be reduced if water levels increase. The volume that would have been available to store floodwaters is used instead to store the increased volumes coming into the wetland. This suggests that the functions related to reducing flooding would also decline because storage is a large component of flood reduction. On the other hand, wetlands in which water is deeper or covers more of the wetland may provide better recharge of groundwater because infiltration depends on the depth of water in the wetland (hydraulic head) and the area that is submerged (Hruby et al. 1999).

The converse can be hypothesized if water levels in wetlands decrease. The potential amount of water that can be stored in a wetland will increase as it becomes drier, thereby increasing the "flood reduction" functions. The function of recharging groundwater would decrease because less water would be present and it would be shallower.

4.4.2 Impacts on Functions that Improve Water Quality from Changing the Amount of Water

Increasing the amount of water in a wetland brings a greater volume of surface water in contact with wetland plants, soils, and the chemical processes that lead to water quality improvement. Increased flooding in wetlands can change residence time, the distribution of aerobic and anaerobic environments, and a variety of microbial and non-microbial chemical processes (Kadlec and Knight 1996). These factors can all change how wetlands remove contaminants.

Because there are so many factors involved in removing individual contaminants it is not possible to generalize the response of a wetland to changes in water levels. Kadlec and Knight (1996) provide further discussion on the many different ways water levels affect the capacity of wetlands to remove toxic compounds. The discussion below provides only a few examples.

For example, the activity of microbes potentially increases conversion of inorganic mercury to the much more toxic form, methyl mercury (Kelly et al. 1997). In this case flooding would reduce the effectiveness of a wetland at improving water quality because the wetland may become a source of this more toxic compound. We do not have specific data about mercury in Washington's wetlands, although mercury is a water quality issue in some waters of the State (e.g., the high levels of mercury found in freshwater fish) (Ecology 2003). We can hypothesize, therefore, that mercury is present in some of the state's wetlands and can be released under anaerobic conditions.

In addition, a change in the rate of nitrogen removal can be hypothesized to result from a shift in the amount of water present in a wetland. In Washington, the area that is seasonally

inundated was judged to be a critical factor in determining nitrogen removal by wetlands (Hruby et al. 1999). If the increase in water levels expands the area that is seasonally flooded, the rates of nitrogen removal will probably increase. If, however, increases in the amount of water in a wetland expand the amount of permanent water at the expense of the areas that were seasonally flooded, the rates of removal can be hypothesized to decrease. Thus, wetlands in which the water regime has been changed will probably have a different rate of nitrogen removal than they had previously.

4.4.3 Impacts on Plants from Changing the Amount of Water

Much of the literature on how changing amounts of water affect plant populations in wetlands of the Pacific Northwest is in terms of changes in the dynamics of water movement (hydroperiod). This concept combines both changes in water levels and changes in how water levels fluctuate (the latter is addressed as a separate disturbance in Section 4.5).

The composition and richness (number of species) of the plant community are influenced by the water in the root zones of wetland plants. This is influenced by:

- The **duration** of saturation (Dicke and Toliver 1990, Merendino and Smith 1991, David 1996, Vivian-Smith 1997, Silverton et al. 1999, Casanova and Brock 2000)
- The **timing** of saturation (Merendino et al. 1990, Squires and van der Valk 1992, Scott et al. 1996, 1997, Gladwin and Roelle 1998)
- The **frequency** of saturation (van der Valk 1994, Pezeshki et al. 1996, 1998, Smith 1996, Pollock et al. 1998, Casanova and Brock 2000)
- The **depth** of water (Casanova and Brock 2000).

Disturbances to any of these factors in a wetland can cause major changes in the distribution and richness of plant species. The response of an individual wetland to such changes, however, is difficult to predict. The existing information indicates that each plant species responds in a different way to changes in water levels. This means that overall the response of the plant community in a wetland will depend on the sum of the responses of the individual species. The following discussion summarizes some of the studies documenting how plant communities change with changes in water levels. It is beyond the scope of this document to provide detailed information on the response of individual plant species.

> Responses of hundreds of plant species to specific hydrologic variables that have been studied are presented in a database at EPA's web site (Adamus and Gonyaw 2000). The database is available at http://www.epa.gov/owow/wetlands/bawwg/publicat.html

The changes in plant communities are linked to differences among plant species in their ability to resist drought and flooding. The life history and physical characteristics of plants play a role (Earnst 1990, Koncalova 1990, Voesenek et al. 1993, Kirkman and Sharitz 1993, Teutsch and Sulc 1997). The characteristics of seed dispersal and germination of plants

relative to water dynamics may have the greatest effect on the relative abundance of species, according to a simulation conducted by Ellison and Bedford (1995) using six years of data from a southern Wisconsin sedge meadow. Some species, such as cattail (*Typha* spp.), are able to keep pace with rising water levels because their stem tissue elongates rapidly and to a greater degree than other species (Waters and Shay 1992, Galatowitsch et al. 1999) or they sprout adventitious roots (Voesenek et al. 1993).

Increases in inundation may change the exposure of plants to competitors and herbivores (Wilson and Keddy 1991) and cause a shift in the location of plant communities within a wetland (van der Valk et al. 1992). The opposite extreme—dehydration—kills plants partly by removing the pathway for taking up nutrients and maintaining tissues. Dehydration may also increase or decrease competition and plant exposure to herbivores (Adamus et al. 2001).

Woody plants are particularly sensitive to prolonged inundation, especially for longer than 80 days (Niswander and Mitsch 1995, Toner and Keddy 1997, Sharitz and Gresham 1997). Their seedlings consequently are most affected during years when flooding occurs at or shortly after the beginning of the growing season, or when flooding persists for more than 40% of the growing season (Toner and Keddy 1997). Annual (as opposed to perennial) species tend to increase proportionately in response to drought and some other severe disturbances (Poiani and Johnson 1989).

Species with small, light seeds seem particularly adept at colonizing mudflats exposed during drawdowns and after disturbances (Poiani and Johnson 1989, Ellison and Bedford 1995). These species tend to emerge early in the season and may be more successful by taking advantage of greater light availability (Toner and Keddy 1997).

Successive years of annual drawdowns can favor the spread of many non-native plant species within wetlands (van der Valk 1994). Dominance of a wetland by just a few species is sometimes a sign that the wetland has experienced prolonged drought or drawdown (Wilcox 1995).

Many species have only a narrow "window" in which they can germinate. For example, there may be only a few weeks when favorable water levels or a temporary lack of competitors must coincide with favorable temperatures and acceptable water quality (Rood et al. 1998).

4.4.4 Impacts on Invertebrates from Changing the Amount of Water in the Habitat

Disturbances to the amount of water in a wetland can cause major changes in the distribution and richness of invertebrate species. Because each species responds in a different way to increases or decreases in water regime, the overall response of the invertebrate community in a wetland will depend on the sum of the responses of the individual species.

Responses of hundreds of invertebrate species to specific hydrologic variables that have been studied (Adamus and Gonyaw 2001) are presented in a database at EPA's web site. The database is available at http://www.epa.gov/owow/wetlands/bawwg/publicat.html

In general, the amounts of water in a wetland influence the distribution and richness of invertebrates by:

- Altering the amount and pattern of horizontal and vertical habitat space available for colonization (Adamus et al. 2001)
- Changing the types of algae and vascular plants that occur, the proportions of these two major food sources for invertebrates, and the seasons in which they occur (Murkin et al. 1992)
- Changing the extent of contact between plants and water, thus influencing attachment space, availability of detrital foods, shade, and shelter (Ross and Murkin et al. 1991, de Szalay et al. 1996)
- Influencing the access of predators (Reice 1991, Martin et al. 1991, Mallory et al. 1994, Johnson et al. 1995, Wellborn et al. 1996)
- Affecting the intensity of competition (Wissinger et al. 1999)
- Causing mortality if complete desiccation or freezing occurs (Layzer et al. 1993)

4.4.4.1 Impacts on Invertebrates from Reducing the Amount of Water in the Habitat

Some of the most dramatic changes to wetland invertebrate communities occur when wetlands that seldom or never dry out completely are subjected to drought or complete drawdown (Adamus et al. 2001). Less dramatic changes to invertebrate communities occur with slight alterations in the timing, duration, predictability, and depth of surface water (Eyre 1992, Giberson et al. 1992).

Drought and drawdown render the less mobile species of invertebrates more vulnerable to predation, as well as causing their direct loss due to desiccation and related factors (e.g., Stanley et al. 1994). Drought also seems to favor non-insect invertebrates, which can increase at the expense of the insect component of the invertebrate community (Hershey et al. 1999). References to drought and drawdown section are for a desert stream (Stanley et al. 1994) and Minnesota (Hershey et al. 1999), respectively. It is reasonable to extrapolate the findings of these studies to eastern Washington, which may have climates and conditions that are somewhat similar to those in the cited literature, but they may not apply to western Washington.

Coupled with the studies that show invertebrate richness increasing with longer periods of inundation, these observations indicate that removing water from a wetland may reduce the species richness of invertebrates.

4.4.4.2 Impacts on Invertebrates from Increasing the Amount of Water in the Habitat

An increase in the amount of water in a wetland seems to change the composition of the invertebrate community. Densities of swimming (nektonic) and bottom-dwelling (benthic) predatory invertebrates do not increase with flooding as much as the numbers of nektonic and benthic herbivores and detritivores. Predatory species can even decrease after flooding (Murkin et al. 1991), and they often increase as drought or drawdown progresses.

Although flooding generally increases the density and richness of invertebrates in wetlands, the increase may be short-lived. For example, flooding of Manitoba marshes (Murkin et al. 1991) to a level 3 feet (1 m) above normal caused a major increase in numbers of nektonic invertebrates in both vegetated and open water areas for only one year. Furthermore, densities of benthic invertebrates increased in flooded vegetation but not in open areas. The biomass of nektonic invertebrates increased only in the vegetated areas (Murkin et al. 1991).

Some researchers have observed that food webs become more complex and taxa numbers increase as wetlands become wetter, such as those that are ponded for longer periods. This has been observed in seasonal wetlands of eastern Washington (Lang 2000). Also, the use of emergence traps in 19 wetlands in King County yielded more taxa from permanently flooded than seasonally flooded wetlands (Ludwa and Richter 2001b), suggesting that wetlands in which the water levels fluctuate more often will have fewer invertebrate species.

These results suggest that disturbances that cause water to remain longer in a wetland will probably increase species richness at first. The long-term effects of such increases, however, are not well understood.

4.4.5 Impacts on Amphibians and Reptiles from Changing the Amount of Water in the Habitat

Most amphibians cannot tolerate prolonged dry periods. Drying of seasonal pools, especially when it occurs ahead of normal seasonal schedules, can greatly diminish the breeding success of amphibians (Rowe and Dunson 1993). This is partly because many amphibian species disperse only short distances (Berven and Grudzien 1990).

Amphibian populations scattered across wetlands of varying depth and water permanence can enable species to survive long-term droughts or floods. The availability of numerous, scattered wetlands can protect amphibians against effects of localized drought. Some frog and toad species living in relatively intact landscapes seem mostly unaffected, at the level of populations, by significant periods of drought (Dodd 1995).

In addition, both prolonged desiccation and extreme floods can increase opportunities for invasion of wetlands by exotic plant species. This change in water regime can impact the suitability of a wetland as habitat for amphibians by changing the structure of the wetland. Patterns of vegetation typically become more homogeneous, prey abundance may decline, and the habitat may become less suitable for amphibians (Ludwa 1994).

Changing the amount of water in wetlands can also impact the populations of reptiles. During a two-year drought in Washington, a local population of painted turtle (*Chrysemys picta belli*) suffered a 70% decline (Lindenman and Rabe 1990). This appeared to be due to both mortality and movement of turtles out of the wetland. Growth of the turtles was suppressed but it recovered as conditions improved. Drawing down the water level in the autumn to allow wetland management, flood control, or for other reasons can cause high mortality among juvenile turtles that are overwintering due to freezing. This occurs if the drawdowns follow abnormally high water levels in late summer that attracted turtles (Galat et al. 1998).

These results indicate that changing the amounts of water in a wetland affects both amphibians and reptiles. Impacts may occur both from lowering the water levels (for example, through ditching, draining, or pumping) or raising the levels through increased flooding as a watershed is developed.

4.4.6 Impacts on Fish from Changing the Amount of Water in the Habitat

Declines in the amounts of water alter the community structure of wetland fish. Fish experience a greater need to use overlapping resources and face an increased risk of predation when wetlands become drier (Adamus et al. 2001). Low water also increases the chance of fish freezing in winter or dying from thermal stress in summer (Adamus et al. 2001).

Sustained drawdowns can also reduce competition among fish that return to wetlands when water levels rise again by temporarily eliminating larval dragonflies and other large invertebrates that normally compete for food with the fish or prey on larval fish (Travnichek and Maceina 1994).

Impacts of increasing water levels on fish in wetlands were not documented in the literature.

4.4.7 Impacts on Birds from Changing the Amount of Water in the Habitat

Disturbances to the amounts of water in a wetland can cause major changes in the distribution and species of birds. As with plants and invertebrates, the overall response of the bird community in a wetland will depend on the sum of the responses of the individual species.

4.4.7.1 Impacts on Birds from Reducing the Amount of Water in the Habitat

Drainage and some other disturbances in the amounts of water in wetlands have been well documented as contributing to the decline of many wetland bird species (David 1994, DeAngelis et al. 1997). In Manitoba, for example, wetland drainage has made breeding and brood-rearing areas for waterfowl less available (Rotella and Ratti 1992). As wetlands are

drained or converted to other land cover types, local densities of wetlands decline and the average distances between individual wetlands increase.

Drought conditions also expose duck nests to greater predation. With drought, plants are less dense and vigorous, and islands that formerly were inaccessible gain new access points (Hallock and Hallock 1993, Jobin and Picman 1997).

Widespread drawdown of water tables reduces the number and perhaps the variety of wetlands and their vegetation communities. This in turn diminishes the richness, density, and breeding success of birds in many individual wetlands and wetland complexes (Higgins et al. 1992, Bethke and Nudds 1993, Bancroft et al. 1994, Greenwood et al. 1995, Dobkin et al. 1998).

4.4.7.2 Impacts on Birds from Increasing the Amount of Water in the Habitat

Increasing the duration of saturation or inundation can change the use of wetlands by a variety of birds. This change can occur when shallow ephemeral ponds are dredged to make areas with longer periods of standing water (such as stock ponds). In the Columbia Basin, Creighton et al. (1997) found an increase in use by several species of diving and dabbling ducks, coots, and terns when shallow, densely emergent wetlands were dredged to create deeper pools of open water. They also documented an increase in the biomass of zooplankton, a food source for several guilds of birds. However, there was a decrease in use by sora (*Porzana carolina*) and Virginia rails (*Rallus limicola*) as well as red-winged blackbirds (*Agelaius phoeniceus*). The use of the excavated habitats by rails was expected to increase over time as emergent vegetation became reestablished in the excavated pools because rails prefer vegetation that is a mix of robust and thin-stemmed species. An increase in use by shorebirds was one short-term benefit. The shorebirds fed on the moist, fresh dredge spoils and exposed unvegetated soils of the newly excavated basins. Once the soils became vegetated, use by shorebirds declined.

On the other hand, while construction of reservoirs raises water levels, this affects birds by eliminating many wetlands through flooding and destabilizing water levels in the remaining wetlands (Nilsson and Dynesius 1994). Associated changes in river morphology influence the species composition of wintering waterfowl (Johnson et al. 1996).

4.4.8 Impacts on Mammals from Changing the Amount of Water in the Habitat

Information on how disturbances to the amount of water in a wetland may affect their ability to provide habitat for mammals was not found. It is not possible at this stage to hypothesize either positive or negative impacts on habitat for mammals because no logical deductions could be made from the available information.

4.4.9 Summary of Key Points

- Impacts of reducing water levels on the habitat functions of wetlands have been documented for invertebrates, fish, birds, and amphibians. All these groups have reduced species richness and abundance when wetlands dry up.
- Impacts of increasing water levels in wetlands on its functions as habitat have been documented for invertebrates and birds. The species richness of invertebrates may increase for a short time if a wetland becomes wetter. The impacts on the populations of birds are mixed. In some cases the richness of birds increases and in some cases it decreases.
- Impacts to the suitability of wetlands as mammal habitat resulting from either increasing or reducing water levels have not been studied.
- Reducing the amount of water changes the distribution of plants in a wetland, but the studies did not address if species richness will increase or decrease. Data suggest that woody species will tend to be replaced by more grass-like species when water levels in a wetland increase.
- Impacts to the hydrologic and water quality functions from either increasing or reducing water levels can only be hypothesized since no information on these topics was found in the literature.

4.5 Impacts from Changing the Fluctuation of Water Levels within a Wetland

A major finding of the Puget Sound Wetlands and Stormwater Management Research Program was that fluctuations in water level are key in determining biological responses. There are different types of fluctuations in water levels in a wetland and these are described in the shaded box below. The researchers found a decline in the biotic diversity of wetlands associated with an increase in water level fluctuations caused by expanding impervious area within the contributing basin (Reinelt et al. 1998, Azous and Horner 2001).

Prolonged inundation (that is, less frequent water level fluctuations) resulting in a lack of oxygen in the soils has been indicated as a factor in changing the biota of wetlands. Although many hydric soils may be anaerobic, changing the length of time the soils are inundated results in prolonged anaerobic conditions and chemical changes in the soils. These changes in soil chemistry influence the survival of vegetation and microbes in the soil that were adapted to shorter periods of inundation (Thom et al. 2001).

Mechanisms for how fluctuations of water levels affect aquatic systems

Richter et al. (1996) developed a method to model "indicators of hydrologic alteration" based on assessing changes in 32 hydrologic parameters. They identified these parameters as being relevant to the biotic integrity of aquatic ecosystems. They divided the parameters into the following five fundamental factors that characterized how fluctuations in water levels influence biotic communities in aquatic systems:

Magnitude. A measure of the availability or suitability of aquatic habitat. It defines such habitat attributes as wetted area or habitat volume, or the position of a water table relative to the rooting zones of wetland or riparian areas.

Timing. The timing of occurrence of a particular water condition. It can determine whether certain life-cycle requirements are met. It can also influence the degree of stress or mortality associated with extreme water conditions such as floods or droughts.

Frequency. Refers to the frequency of occurrence of specific hydrologic conditions, such as droughts or floods. It may be tied to events such as the reproduction or mortality of various species, thereby influencing population dynamics.

Duration. The length of time over which a specific hydrologic condition exists. It may determine the success of the life cycle of a particular species or the accumulation of stressful effects.

Rate of change. In hydrologic conditions may be linked to stranding of individuals (in isolated pools or along a wetted edge). It may also be related to the ability of sensitive species to maintain root contact within the phreatic zone (the portion of the soil that is influenced by proximity to the groundwater table).

4.5.1 Impacts on Hydrologic Functions from Changing the Fluctuations in Water Levels

The literature did not provide explicit information on possible impacts of changes in water level fluctuations on factors within a wetland that affect its hydrologic functions. It is not possible at this stage to hypothesize either positive or negative impacts on hydrologic functions because no logical deductions could be made from the available information. The major questions that need to be addressed include:

- Will changes in the frequency or amplitude of water level fluctuations change the flood storage capacity of a wetland?
- Will changes in the frequency or amplitude of water level fluctuations change the way in which a wetland reduces water velocity?
- Will changes in the frequency or amplitude of water level fluctuations change the way in which a wetland recharges groundwater?

4.5.2 Impacts on Functions that Improve Water Quality from Changing the Fluctuations in Water Levels

How changing fluctuations in water levels impact the ability of wetlands to improve water quality was not detailed in the literature. It is not possible to hypothesize either positive or negative impacts on water quality functions because no logical deductions could be made from the available information. The major questions that need to be addressed include:

- Will changes in the frequency or amplitude of water level fluctuations change how a wetland traps sediment?
- Will changes in the frequency or amplitude of water level fluctuations change the way in which a wetland removes nitrogen?
- Will changes in the frequency or amplitude of water level fluctuations change the way in which a wetland captures or transforms toxic compounds?

4.5.3 Impacts on Plants from Changing the Fluctuations in Water Levels

In general, the amplitude and rate of water level fluctuations have been found to influence the species composition, biomass, and germination of plants (Hudon 1997, Shay et al. 1999). Furthermore, the timing of inundation and duration throughout the seasons also influences plant species richness and survival (Ewing 1996, Reinelt et al. 1998, Owen 1999, Azous et al. 2001). If these hydrologic factors change as a result of human activities as described in Chapter 3, one can then hypothesize changes in plant communities.

Researchers in the Puget Sound regions correlated a decline in plant species richness in urbanized watersheds where water level fluctuations had increased (Azous and Cooke 2001). Among 26 wetlands in the Seattle area, the degree of seasonal fluctuation in water level was negatively associated with richness found in emergent and shrub wetlands. However, it had no statistically significant effect on species richness in forested wetlands (Cooke and Azous 2001). These authors found that fluctuation during the early spring seemed to have an especially detrimental effect on plant richness in the emergent and shrub wetlands.

Reinelt et al. (1998) found that the development of plant communities in lowland wetlands of Puget Sound was related to water level fluctuations and depth of inundation during the early growing season. They noted that shifts in the "hydrologic profile" of the wetland caused a subsequent shift in the species composition of the wetland's plants. The emergent and scrub-shrub communities of the wetland tended to have lower plant richness when average, annual water-level fluctuations increased to over 8 inches (20 cm).

Azous and Horner (2001) determined that the duration of flooding, as well as depth, also strongly influenced plant diversity. They noted greatest plant diversity when:

- Flooding events were less than 0.5 feet (0.2 m) above predevelopment levels
- Floods were limited to an annual average of three or fewer events per month
- The cumulative duration of flooding was less than six days per month above predevelopment averages

On the other hand, a lack of fluctuation in water level can be just as damaging as excessive fluctuation to some wetland plant species (Rood and Mahoney 1990). This is because many species need a period of desiccation in order to germinate. Furthermore, the loss of wet-dry cycles in floodplain wetlands that result from the construction of dams favor exotic species that replace the native plant community (Bunn and Arthington 2002).

On the other hand, evidence from some studies suggests that the relative tolerance to increases in water level fluctuations is greatest among several non-native or invasive species (Figiel et al. 1995, Haworth-Brockman and Murkin 1993, King and Grace 2000). Increases in water level fluctuations and duration of inundation favor generalist plants (plants that are found under a wide range of environmental conditions) in the Pacific Northwest (Azous et al. 2001).

These results indicate that changes to water level fluctuations in wetlands are likely to result in shifts in the composition, distribution, and abundance of plants, especially in situations where there is a relatively stable hydroperiod with low level fluctuations. Furthermore, either decreases or increases in water level fluctuations will probably facilitate the invasion of non-native or "aggressive" native species by increasing the level of disturbances to which plants are subject.

4.5.4 Impacts on Invertebrates from Changing the Water Level Fluctuations in the Habitat

In the Northwest, researchers have observed a decline in the number of invertebrate species in wetlands as the impervious area in the basin increases (Ludwa 1994, Hicks 1996, Ludwa and Richter 2001a, Thom et al. 2001). Since changes in the fluctuations of water levels are a major disturbance that results from an increase in impervious surface, it can be hypothesized that the decline in the Northwest is a result of this disturbance. Information from other parts of the United States seems to confirm this hypothesis.

The densities of some invertebrate species can be decimated by rapid water level fluctuations, especially when the fluctuations are more frequent and severe than historically encountered in the wetland. For example, Missouri floodplain pools that experience large fluctuations in water level during major floods tend to have lower invertebrate density (Magee et al. 1993). Repeated exposure to desiccation in a short period of time can lead to a marked reduction in the density of invertebrates. In an Arizona stream that experienced 12 flash floods between August and December of a single year, densities of all invertebrates

were reduced by 75% to 100% (Boulton et al. 1992). In particular, the numbers of water spiders, midges, and some caddisflies, mayflies, and snails declined.

A number of studies have found that reducing fluctuations in streams by maintaining minimum water levels (such as in reservoirs) can increase invertebrate densities in the part of an adjacent wetland that is not permanently inundated (Weisberg et al. 1990, Troelstrup and Hergenrader 1990).

4.5.5 Impacts on Amphibians and Reptiles from Changing the Water Level Fluctuations in the Habitat

In Puget Sound wetlands, amphibian species richness was negatively correlated with the percent of impervious cover in a contributing basin. The primary cause is increased water level fluctuation (Richter and Azous 2001a). The richness of amphibians declined to less than three species when water level fluctuations increased to over 8 inches (20 cm) (Richter and Azous 2001a, Thom et al. 2001). Chin (1996) concluded that the reduced richness of amphibians was correlated with a reduction in the diversity of wetland plants that resulted from increases in water level fluctuations.

Increases in fluctuation of water levels also affect amphibians by (1) stranding egg masses when water levels drop, and (2) reducing the thin-stemmed emergent plant species on which amphibians lay their eggs. Unpublished work by Richter (K. Richter, King County, personal communication 2002) in western Washington found that amphibians preferred thin-stemmed vegetation on which to lay their egg masses. Greater water level fluctuation directly affects amphibian egg survival and causes changes in plant species, reducing the thin-stemmed emergent species used by amphibians for egg laying (Chin 1996).

No correlations were found between the richness of amphibian species and a variety of other factors including wetland size, distance to breeding habitats, presence of predators, and number of vegetation classes (Richter and Azous 2001a). The most significant factor affecting species richness was mean water level fluctuation, with 8 inches (20 cm) mean annual fluctuation being a threshold for lentic breeding species (those that breed in stagnant or slow-moving waters such as ponds and wetlands). Lentic breeding amphibians appear to be affected by increases in the duration and frequency of flooding and increased discharge rates resulting from the greater frequency and magnitude of storm peaks in urban watersheds (Richter and Azous 2001a).

Amphibian populations in western Washington generally experience impacts in contributing basins with increasing amount of impervious surface (Booth and Reinelt 1993). A more recent study documented that watersheds with less than 15% total impervious area had three or more amphibian species, whereas most watersheds with more than 25% impervious area had less than three species (Chin 1996). Chin (1996) concludes that changes in water level fluctuations and maximum water levels during spring breeding and embryo development are the primary adverse effects of increased impervious surface.

4.5.6 Impacts on Fish from Changing the Water Level Fluctuations in the Habitat

No specific information was found on how changing fluctuations in water levels impact the ability of wetlands to provide habitat for fish. It is not possible to hypothesize either positive or negative impacts on habitat for fish because no logical deductions could be made from the available information.

4.5.7 Impacts on Birds from Changing the Water Level Fluctuations in the Habitat

General observations have indicated a decline in bird richness for wetlands located in a contributing basin that is developed or developing. Richness was not reduced in contributing basins that remained rural or relatively undeveloped over the course of the Puget Sound Wetlands and Stormwater Management Research Program (Richter and Azous 2001b, Thom et al. 2001). These observations have not specifically been correlated with changes in the fluctuation of water levels, although it can be hypothesized that some of the changes observed are a result of changes in water level fluctuations because this is one of the major disturbances caused by impervious surface (see Chapter 3).

4.5.8 Impacts on Mammals of Changing the Water Level Fluctuations in the Habitat

No explicit information on how changing fluctuations in water levels will impact mammal populations in wetlands was presented in the literature. It is not possible to hypothesize either positive or negative impacts on mammal populations because no logical deductions could be made from the available information.

4.5.9 Summary of Key Points

- No information was found on the impacts to the hydrologic and water quality functions of wetlands resulting from altered fluctuations in water levels.
- Impacts on habitat for invertebrates and amphibians resulting from changes in how water levels fluctuate in wetlands have been documented. Both groups of wildlife exhibit reduced species richness and abundance when wetlands are subject to increased fluctuations in water levels. Impacts to the suitability of wetlands as habitat for mammals, fish, and birds have not been documented.
- Increasing and decreasing fluctuations in water levels also reduce plant richness in wetlands.

4.6 Impacts from Changing the Amount of Sediment Coming into a Wetland

The sporadic movement of sediment in and out of wetlands is a disturbance that also occurs in the absence of human activities. For example, the persistence of some wetlands (i.e., certain riverine and lakeshore wetlands) depends on a sporadic deposition of sediment (Mistch and Gosslink 2000). On the other hand, depressional wetlands are natural sinks for sediments because they are the low points in the topography (Brinson 1993b), and this is a function they perform with or without the presence of human activities. Negative impacts to wetlands occur when the amount of sediment coming into a wetland either increases or decreases from the levels that are present in the absence of human activities (see Mistch and Gosslink 2000 for general references to this process).

4.6.1 Impacts on Hydrologic Functions from Changing the Amount of Sediment

Despite a lack of explicit information on impacts that sedimentation may have on hydrologic functions, it is possible to hypothesize that increases in sediment load to a wetland will reduce the amount of water it can store. For every cubic yard of sediment deposited in a wetland and not transported further, the storage capacity of water is reduced by a similar amount. This means that depressional wetlands along stream corridors with high inputs of sediment may lose much of their ability to store surface waters during floods. A similar hypothesis can be made for depressional wetlands with no surface outflow. Increases in sediment load to such wetlands can reduce the storage capacity.

4.6.2 Impacts on Functions that Improve Water Quality from Changing the Amount of Sediment

No information was found on how changing the sediment load to a wetland might change the water quality functions in wetlands. It is not possible to hypothesize either positive or negative impacts on the water quality functions because no logical deductions could be made from the available information.

4.6.3 Impacts on Plants from Changing the Amount of Sediment

Accelerated sediment deposition or erosion can tax the ability of plant communities to adapt (Kantrud et al. 1989, Jurik et al. 1994, Wang et al. 1994). Sediments have been found to impact plant communities in wetlands in several general ways:

- **Burying seeds, leaves, or plants.** Sedimentation can bury established vegetation and seed banks (Adamus et al. 2001). The burial of leaves prevents photosynthesis and restricts gas exchange through foliage (Ewing 1996). Buried plants expend energy

elongating their shoots in an attempt to outpace sedimentation, seeking oxygen and light, and consequently may be less robust.

- **Changing the depth of habitats.** Over the long term, sedimentation can shrink shallow wetlands or reduce the depth of ponds that previously were too deep to support many wetland plants. Such long-term changes in water depth or relative elevation also result in shifts in species composition, as has been documented in the Mississippi River floodplain (Adamus et al. 2001).

- **Inhibiting germination.** Seeds of the most sensitive species often fail to germinate when buried (Dittmar and Neely 1999). The addition of sediment has been found to reduce germination rates of herb species in wetlands by 34% (Neely and Wiler 1993), 80% (Jurik et al. 1994), and 90% (Wang et al. 1994) depending on the species involved. In general, the species with larger seeds appear to be better able to survive burial (Dittmar and Neely 1999, Jurik et al. 1994, Wang et al. 1994).

  Less than 0.5 inch (1 cm) of sediment can inhibit germination of cattails (*Typha* sp.), barnyard grass (*Echinocola crusgalli*), rice cutgrass (*Leersia oryzoides*), and sedges (*Carex* sp.) (Jurik et al. 1994). Sedimentation inhibits the germination of cattail (*Typha latifolia*) seeds more than seeds of bur-reed (*Sparganium eurycarpum*) (Neely and Wiler 1993). Germination of cattail (*Typha* x *glauca*) seeds decreased by 60% to 90% when sediment loads of less than 0.5 inch (0.2 to 0.4 cm) were applied to the surface of the soil (Wang et al. 1994).

  In contrast, burial by 1 inch (2 cm) of sediment does not interfere with germination of several non-native plant species (Blackshaw 1992, Reddy and Singh 1992).

- **Reducing survival of seedlings.** Excessive sedimentation can reduce the survival of seedlings (Jurik et al. 1994). For example, the density of cattail seedlings and their biomass decreased as sediment loads increased from 0.08 to 0.5 inch (0.2 to 1.0 cm). One study found a fourfold greater density of annuals (vs. perennials) in some heavily sedimented sites (Neely and Wiler 1993). Older and larger seedlings were more tolerant of burial (Wang et al. 1994).

- **Favoring species more tolerant of sediment.** Sedimentation impacts individual wetland species in different ways. The composition of the plant community will therefore change as the most sensitive species are suppressed by the sediment while the more tolerant ones thrive. Effects of sedimentation on particular wetland plant species are not well documented (van der Valk and Jolly 1992) but findings relevant to wetland species found in Washington are discussed here.

  Many mature plants, and especially woody species, apparently are not harmed by a small amount of sedimentation (Wang et al. 1994). Adult plants of wild celery (*Vallisneria americana*) tolerated burial to depths of up to 4 inches (10 cm) but none survived burial under sediment depths of 10 inches (25 cm) (Rybicki and Carter 1986). Among woody plants, saplings of red alder (*Alnus rubra*) tolerated burial less well than those of Oregon ash (*Fraxinus latifolia*) (Ewing 1996).

Growth of the invasive reed *Phragmites australis*, however, typically keeps pace with moderate rates of sedimentation (Pyke and Havens 1999). However, seeds, seedlings, and plants that have evolved in wetland types in which sedimentation is rare (such as bogs) may be highly sensitive to burial. The size of particles that are being deposited, not just their amount, may also influence plant survival (Dittmar and Neely 1999).

A recent study by Mahaney et al. (2004) found that the response of plants to increases in sedimentation depends on the hydrogeomorphic class of the wetland. Increases in sedimentation reduced the emergence of four species found in riparian depressions but only affected one species in slope wetlands and none in headwater floodplains.

4.6.4 Impacts on Invertebrates from Changing the Amount of Sediment in the Habitat

In general, increased amounts of sediment can reduce the richness and density of invertebrates and alter their species composition. Excessive sedimentation affects invertebrates through several mechanisms (reviewed in Adamus et al. 2001):

- Burial of detritus and algae, which are important food sources
- Increase in the time required for invertebrates to move through deposited sediment and collect scarce food items
- Reduced flow of water through soil particles, which is necessary to supplying invertebrates with adequate dissolved oxygen
- Mortality of plants that otherwise provide attachment structures and shelter to invertebrates

Some studies have linked changes in invertebrate communities to the development of watersheds (e.g., Hogg and Norris 1991, Ludwa 1994, Carlisle et al. 1998, Ludwa and Richter 2001a). Development often is accompanied by increased export of sediment to water bodies.

Many invertebrate communities in wetlands are adapted to occasional deposition of small amounts of sediment, whereas constant or severe deposition causes major changes. The following bullets summarize some of the studies that have documented impacts of sediment on individual invertebrate species, as well as groups of species, many of which are found in Washington.

- Once deposited, sediments can further damage wetland invertebrate communities if they are re-suspended by wind mixing or fish, making the water turbid. For example, bottom-feeding carp (*Cyprinus carpio*) noticeably increase turbidity, both directly (as they move along the bottom) and by consuming aquatic plants that otherwise would stabilize and trap sediments (Lougheed et al. 1998). The biomass of planktonic invertebrates declined in Utah ponds after introduction of carp (Huener and Kadlec 1992).

- In some instances, invertebrate density and perhaps richness can increase over the long term if sedimentation replaces coarser substrates with finer substrates that better support establishment of rooted plants. In temporarily flooded prairie pothole wetlands, only caddisflies seemed relatively unaffected by surrounding land use that generated sediments. Ostracods (seed shrimp), cladocerans (water fleas), and some snails (planorbiids, lymnaeids, physids) were diminished, presumably in part because of sedimentation (Euliss and Mushet 1999).

- Burrowing, tube-forming worms and midges commonly predominate where sediments accumulate (Magee et al. 1993). Filter-feeding species and those that graze on the bottom are most sensitive (Lougheed and Chow-Fraser 1998). However, invertebrate size and behavior also influence their tolerance to sediments (McClelland and Brusven 1980). On the other hand, substrates newly created by sedimentation may attract tolerant individuals and species that are poor competitors on older, more crowded substrates (Soster and McCall 1990).

- Severe and rapid sedimentation is inevitably lethal to nearly all aquatic invertebrates. In North Dakota, wetlands surrounded by cropland were virtually devoid of the resting eggs of zooplankton, whereas such eggs were abundant in wetlands surrounded by mostly natural grassland, which presumably minimized erosion and sedimentation (Euliss and Mushet 1999).

- Unionid mussels (mussels in the family Unionidae) are sensitive to increased sedimentation (Goudreau et al. 1993, Box and Mossa 1999). Numbers of the swamp fingernail clam (*Musculium partumeium*) and amphipods were reduced in willow wetlands in northeastern Missouri where 2 to 4 inches (5 to 10 cm) of sediment had been recently deposited (Magee et al. 1993).

- Sediments may clog the filter feeding mechanisms of some species and limit light penetration. This would adversely impact phytoplankton and other primary producers, with a subsequent adverse impact on food chains (Euliss and Mushet 1999).

- Sediments also potentially buries invertebrate eggs deposited in the substrates of wetlands (Euliss and Mushet 1999).

4.6.5 Impacts on Amphibians and Reptiles from Changing the Amount of Sediment in the Habitat

Few studies of the impacts of increases in the deposition of sediment on amphibians and reptiles have been conducted in wetlands. On one hand, some species require soft sediments as hibernation sites. For example, painted turtles (*Chrysemys picta*) used sediments 1.6 to 3 feet (0.50 to 0.95 m) thick in an Ontario pond (Taylor and Nol 1989). On the other hand, excessive sediments, when stirred, impair light penetration of the water column and thus can inhibit growth of algae and especially submersed aquatic plants, which provide cover and attachment sites for amphibian eggs.

4.6.6 Impacts on Fish from Changing the Amount of Sediment in the Habitat

No recent studies on the impacts of sediment on habitat for fish in North American wetlands or lakes were found. Most of the studies on the impacts of sediment on fish populations have been done in streams, especially as it concerns the growth and reproduction of salmonids in the Pacific Northwest. This information was reviewed and synthesized in Knutson and Naef (1997). The conclusion reached by Knutson and Naef quoted below can also apply to wetlands because streams are often considered a part of wetlands:

> *Sedimentation in fish-bearing waters affects habitat quality and fish survival in a number of ways. Stream bottoms covered with fine sediments are no longer suitable for spawning. Sediments cover and suffocate fish eggs and fry. High sediment deposits also block fish passage to upper spawning reaches. Suspended sediments clog the gills of fish, decrease dissolved oxygen levels, inhibit fish feeding and growth, and suppress macro-invertebrate food sources.*

4.6.7 Impacts on Birds from Changing the Amount of Sediment in the Habitat

Little information was found on how sedimentation impacts the habitat that a wetland provides for bird communities. One can hypothesize, however, that sedimentation can impact birds by altering structure of vegetation (see Section 4.6.3) that provide food for herbivorous birds or those that prey on invertebrates (see Section 4.6.4). In one case, the densities of breeding dabbling ducks were positively correlated with wetland turbidity in ponds in the interior of British Columbia (Savard et al. 1994).

4.6.8 Impacts on Mammals from Changing the Amount of Sediment in the Habitat

No information was found on how sedimentation might change the habitat that a wetland provides for mammals. As with birds, however, one can hypothesize that sedimentation can impact mammals by altering habitat structure or changing the abundance or availability of prey items.

4.6.9 Summary of Key Points

- No information was found on possible impacts of sedimentation on the functions of wetlands that improve water quality.
- Increasing sedimentation will decrease plant richness and tends to favor the more invasive types that tolerate disturbance.

- Impacts of increased amounts of sediment on the habitat functions of wetlands have been documented for invertebrates, amphibians, and fish. All of these groups generally have reduced species richness and abundance when wetlands are subject to increased sedimentation. In some cases, however, where the sediments coming into a wetland are finer than existing sediments, the number of invertebrate species may increase. Impacts from sedimentation on the suitability of wetlands as habitat for mammals and birds have not been documented.

4.7 Impacts from Increasing the Amounts of Nutrients Coming into a Wetland

The major nutrients for plant growth, phosphates, nitrates, and ammonium, can be transported into aquatic systems and impact the functions performed by wetlands. These nutrients are carried in water in dissolved forms or adsorbed onto sediment. The element phosphorus is usually the limiting nutrient for plant growth in freshwater aquatic systems (Newton 1989, Mitsch and Gosselink 2000). Because it is the limiting factor, phosphorus in the presence of the other critical element, nitrogen, allows expansive growth of phytoplankton, algae, and larger plants in aquatic systems when it is available in higher quantities.

Excessive algal growth is unsustainable, and when the algae blooms die, their decomposition causes the available dissolved oxygen to be consumed. The undesirable growth of vegetation caused by high concentrations of plant nutrients in bodies of water is called *eutrophication*. Eutrophication is defined as the process by which a body of water becomes enriched in dissolved nutrients (as phosphates) that stimulate the growth of aquatic plant life usually resulting in the depletion of dissolved oxygen (Merriam Webster online http://www.m-w.com/cgi-bin/dictionary?book=Dictionary&va=eutrophication accessed October 14, 2004).

Excess phosphorous and nitrogen, therefore, often leads to eutrophication with subsequent mortality of the aquatic organisms that require oxygen (Newton 1989, Mitsch and Gosselink 2000). Wetlands with areas of water on the surface can therefore become eutrophic if they receive excessive amounts of phosphorus and/or nitrogen.

4.7.1 Impacts on Hydrologic Functions from Increasing the Amounts of Nutrients

It is possible that the stimulation of plant growth by excess nutrients could increase the density of plants in the wetland. A thicker stand of vegetation can be expected to provide more resistance to flood flows than a thinner one (Adamus et al. 1991, Hruby et al. 1999). Therefore, excess nutrients might indirectly improve the reduction in velocity that a wetland provides during floods. The literature did not provide any other information on how nutrients might affect the hydrologic function of wetlands.

4.7.2 Impacts on Functions that Improve Water Quality from Increasing the Amounts of Nutrients

Some research indicates that excessive nutrients from agricultural operations may reduce the normal ability of wetland microbes to detoxify particular pesticides (Kazumi and Capone 1995, Chung et al. 1996, Entry and Emmingham 1996). Adding nitrogen to riparian wetlands may potentially compromise the long-term ability of the system to remove nitrogen via denitrification (Ettema et al. 1998). Other information on this topic was not documented in the literature.

However, several avenues of research could be combined to make some hypotheses about impacts. The addition of nutrients to acidic bogs results in changes in plant communities. The plant community that maintains the high acidity in the bog may change to one that maintains a more neutral pH. These changes might then alter several aspects of chemistry in the wetland that affect its ability to improve water quality. The rate of nitrification will probably increase because, as noted by Mitch and Gosselink (2000), low pH inhibits denitrifying bacteria. The change in pH will also probably change the ability of the wetland to bind different toxic metals and other compounds. (See the discussion in Chapter 2 on how pH is linked to the ability of a wetland to bind different pollutants.)

4.7.3 Impacts on Plants from Increasing the Amounts of Nutrients

Excessive nutrients can affect wetland plants in a variety of ways including:

- Shifting the species composition away from species that take up nutrients slowly, to those that are able to exploit nutrient pulses more rapidly or which have high nutrient requirements (Hough et al. 1989, Arts et al. 1990, Gopal and Chamanlal 1991, Wetzel and van der Valk 1998)

- Triggering algal blooms that can shade out many submersed herbaceous plants (Crowder and Painter 1991, Stevenson et al. 1993, Srivastava et al. 1995, Short and Burdick 1995)

- Causing dead plant material to accumulate faster than it can decompose completely, thus altering understory and soil structure (Neill 1990b, Craft and Richardson 1993)

Such changes usually result in long-term changes in the distribution and richness of plants within the wetland. Over the long term, nutrient additions to most wetlands tend to reduce species richness and increase the dominance of a few species. Often, non-native species are most capable of invading rapidly changing environments. Consequently they frequently come to dominate some nutrient-enriched wetlands (Adamus et al. 2001).

Increases in plant litter can smother other plants when the fast growing species die, thus helping maintain the dominance of species that exploit nutrients the most (Adamus et al. 2001). For example, the addition of nitrogen and phosphorus fertilizers to a marsh

dominated by cattail (*Typha glauca)* and the grass *Scolochloa festucacea* during two growing seasons resulted in increased biomass of both species. However, the biomass of *S. festucacea* declined in the second year due to accumulated litter of *T. glauca* (Neill 1990b).

The plants in bogs and other nutrient-poor wetlands are logically the most sensitive to nutrient additions (Moore et al. 1989). The increased availability of nutrients allows grasses and common opportunistic plants to out-compete rare plants (such as sundews, orchids, and pitcher plants) that are adapted to nutrient-poor conditions. For example, in Appalachian peat bogs, the spatial dominance of bristly dewberry (*Rubus hispidus*) was positively related to nutrient levels, but dominance of the Ericaceae shrubs was negatively related (Stewart and Nilsen 1993).

Many aquatic plant species respond to nutrient additions with increased growth, biomass, and productivity. Growth responses to enrichment have been documented for about 80 wetland-associated species in North America. Of these, most have tolerated enrichment or responded to enrichment with increased biomass or growth (Adamus and Gonyaw 2000).

> Information on the response of many individual plant species to nutrients can be found in the National Database of Wetland Plant Tolerances at: http://www.epa.gov/owow/wetlands/bawwg/publicat.html#database1

4.7.4 Impacts on Invertebrates from Increasing the Amounts of Nutrients in the Habitat

Excessive nutrients can cause long-term and short-term shifts in invertebrate communities. The information available suggests that excess nutrients can result in both decreases and increases in species richness as well as changes in the groups of invertebrates found. The direction of the change depends on how the nutrients impact the vegetation and soils that are the main habitat for invertebrates. Findings from the literature include:

- **Increased richness of invertebrates.** Up to some point, nutrient inputs to wetlands can lead to increased invertebrate richness, as more food sources become available to predatory invertebrates (Rader and Richardson 1992, Campeau et al. 1994, Cieminski and Flake 1995, Gernes and Helgen 1999).

- **Reduced richness of invertebrates.** Invertebrate richness in a series of highly enriched wastewater wetlands was found to be lower than in a less enriched reference wetland (Nelson et al. 2000).

- **Changes in the types of invertebrates.** In some cases excess nutrients result in the increased dominance of certain kinds of algae. Invertebrates that specialize in feeding on these algae, or that characteristically find shelter and attachment sites in the aquatic plants, then have an advantage and can become dominant (Murkin et al. 1991, Campeau et al. 1994). Exposure to organic enrichment and eutrophication frequently causes an increase in grazers (such as Tanypodinae midges), as well as

other herbivores, species that feed on detritus, predators, and "miners" that burrow into plants. These are groups that typically increase with increasing growth of algae growing on the bottom and emergent aquatic plants (Campeau et al. 1994). A study of four lacustrine wetlands bordering Lake Michigan also found that midge communities shifted across nutrient gradients (Murkin et al. 1992, Campeau et al. 1994).

- **Increased density of invertebrates.** Total invertebrate density increases with increased nutrients, as algal production becomes less of a limiting factor in the invertebrate community (Murkin et al. 1992, Campeau et al. 1994).

- **Changes in the bioaccumulation of metals by invertebrates.** Nutrients appear to influence the tendency of aquatic invertebrates to accumulate heavy metals and the type of metals that are accumulated. For instance, zinc, iron, and manganese concentrations were higher in midges from nutrient-rich wetlands, whereas high copper concentrations were found in midges from nutrient-poor wetlands (Bendell-Young et al. 2000). This may be due at least partly to the bioavailability of various metals being influenced by oxygen conditions in the sediment, which in turn are partly the result of decomposition of algal blooms triggered by high concentrations of nutrients (Adamus et al. 2001).

Information on the response of many individual invertebrate species to enrichment can be found in the National Database of Invertebrate Tolerances at: http://www.epa.gov/owow/wetlands/bawwg/publicat.html#database1

4.7.5 Impacts on Amphibians and Reptiles from Increasing the Amounts of Nutrients in the Habitat

The review of the literature indicates that amphibians can be impacted by the input of nutrients. No studies were found on impacts on reptiles.

Amphibians in the Northwest can be directly impacted by the input of nitrates. Five amphibian species in Oregon showed both sublethal responses and mortality following laboratory applications of nitrate. These studies indicated that the EPA nitrate criteria for drinking water of 10 milligrams per liter (mg/l) and/or for protection of warmwater fish are inadequate to protect these amphibians (Marco et al. 1999). In Texas, playa wetlands receiving nutrient-laden effluent from feedlots were devoid of amphibians found in natural playas (Chavez et al. 1999). Experiments indicated that effluent had to be diluted to less than 3% strength in order to minimize adverse effects on the leopard frog (*Rana pipiens*).

Indirect impacts of excessive nutrients can also be important to amphibians. Shifts in seasonal timing and amount of nutrients that enter a wetland can, over a period of years, increase the relative dominance of algae and/or emergent plants at the expense of submersed plants. This in turn can reduce the availability of submersed plants as attachment substrates for amphibian eggs and as cover for larvae (Beebee 1996).

Excess nutrients can also diminish dissolved oxygen levels (Tattersall and Boutilier 1999), alter the abundance of aquatic predators, and shift the algal and invertebrate foods available to amphibians (Horne and Dunson 1995). As a result, species composition and sometimes species richness of amphibian communities can decline as eutrophication becomes severe. However, well designed studies of such effects are few.

4.7.6 Impacts on Fish from Increasing the Amounts of Nutrients in the Habitat

No information was found documenting direct impacts of excess nutrients on fish in wetlands. However, the secondary impacts of eutrophication such as oxygen depletion do affect fish. Much of the literature deals with impacts of low oxygen in streams (for a review see Knutson and Naef 1997), and it can be assumed that the impacts of low oxygen in wetlands will be similar.

As mentioned previously, the increased plant production that results from added nutrients often results in low oxygen levels when the plant material dies and starts to decompose. Many fish species suffer from reduced levels of dissolved oxygen, and feeding habits also may shift. To some degree, fish families can be grouped according to their susceptibility to oxygen deficiencies. Salmonids and coregonids (whitefish) require high levels of dissolved oxygen, whereas cyprinids (a large family that includes carp and goldfish) often tolerate low dissolved oxygen levels (Harper 1992). Thus the species composition and richness may change depending on the initial state of the wetland and the duration and magnitude of the eutrophication.

4.7.7 Impacts on Birds from Increasing the Amounts of Nutrients in the Habitat

Eutrophication can indirectly impact the composition of the wetland bird community by altering the vegetation structure and availability of prey. In general, moderately elevated nutrient levels also spur the growth of submersed plants that provide food for ducks, as well as supporting more aquatic insects that are especially important as food for ducklings and aerial foragers like swallows. However, excessive nutrients cause algal blooms that can kill fish eaten by birds, reduce the growth of plants growing on the bottom by blocking light, and reduce visibility of other food items under the water surface.

Studies that have documented changes in the bird community related to excess nutrients are summarized below:

- Excessive nitrates have been implicated in deaths of some frogs (see Section 4.7.5). Frogs are a significant prey item for some wetland birds (Adamus et al. 2001).
- Northern shoveler (*Anas clypeata*) and eared grebe (*Podiceps nigricollis*) were positively associated with phosphorus in a survey of wetlands in interior British Columbia (Savard et al. 1994).

- The abundance and biomass of water-birds were positively correlated in 46 Florida lakes with levels of phosphorus, nitrogen, and chlorophyll. There also was a positive correlation of water-bird richness with phosphorus, after accounting for nutrients contributed to the lakes by the birds themselves (Hoyer and Canfield 1994).

- Total density of dabbling ducks was correlated positively with total dissolved nitrogen (Savard et al. 1994).

- The parasitic nematode *Eustrongylides ignotus*, which has only been found in disturbed and enriched wetlands (Spaulding and Forester 1993), negatively affects the health of adult wading birds and the survival of their nestlings (Spaulding et al. 1993).

4.7.8 Impacts on Mammals from Increasing the Amounts of Nutrients in the Habitat

No information was found on impacts from increases in nutrients on the habitat of mammals in wetlands. It can be hypothesized, however, that, if eutrophication results in anoxic conditions that are lethal to the prey of mammals (e.g., fish and some amphibians), the community composition may shift from predator species (such as otter or mink) to vegetarian or invertebrate-eating species and opportunists (such as muskrat).

4.7.9 Summary of Key Points

- Some impacts to the hydrologic functions from increased nutrients can be hypothesized because the increased growth of plants resulting from increased nutrients may provide better resistance to the movement of flood waters.

- Some impacts to the functions of improving water quality have been reported. These include a potential reduction in the ability of wetlands to detoxify pesticides and to remove nitrogen as a pollutant. Impacts from increased nutrients can also be hypothesized for bogs. The ability of bogs to bind toxic metals may be reduced but their ability to remove nitrogen may be increased.

- Increasing nutrients will stimulate plant growth and may change the composition of the species present.

- Impacts of increased amounts of nutrients on the habitat wetlands provide have been documented for invertebrates, amphibians, and birds. Excess nutrients can result in both an improvement in the habitat through the production of food and a reduction in habitat through eutrophication. The actual impacts depend on local conditions in the wetland. Impacts to the habitat for fish and mammals can be inferred because eutrophication causes reductions in the levels of oxygen in the water with resultant impacts to both water quality and the food sources for these two groups.

4.8 Impacts from Introducing Toxic Contaminants to a Wetland

4.8.1 Impacts on Hydrologic Functions from Toxic Contaminants

Contaminants are chemical compounds, solutions, or particles introduced into the environment that change how the environment or the organisms living there function. Toxic contaminants are poisons that specifically impact the growth and reproduction of living organisms.

No explicit information was found in the literature on the possible impacts of toxicity from contaminants on the hydrologic functions provided by wetlands (storing flood waters, reducing erosion, and recharging groundwater). It is not possible at this stage to hypothesize either positive or negative impacts on hydrologic functions because no logical deductions could be made from the available information.

4.8.2 Impacts on Functions that Improve Water Quality from Toxic Contaminants

Information on how toxic compounds affect the function of wetlands to remove pollutants is sparse. It can be hypothesized, however, that an input of low levels of toxic compounds may stimulate the ability of a wetland to detoxify pollutants. Some microbial species biodegrade particular contaminants and their abundance is increased in the presence of low levels of the contaminants. These species can flourish in some wetlands that are only mildly or moderately contaminated.

Contaminants that can be processed by microbes when concentrations are low to moderate include copper (Farago and Mehra 1993), mercury (Marvin-Dipasquale and Oremland 1998), selenium (Steinberg and Oremland 1990, Azaizah et al. 1997), cadmium (Sharma et al. 2000), manganese (Sikora et al. 2000), and petroleum (Nyman 1999, Megharaj et al. 2000).

4.8.3 Impacts on Plants from Toxic Contaminants

Most plant species are relatively tolerant to toxic contaminants. Impacts usually result from the effects of contaminants on plant metabolic pathways, enzymatic reactions, and growth (Fitter and Hay 1987). Symptoms of toxicity can include reduced growth; small, discolored, or dying leaves; early leaf fall; and stunted or suppressed growth of roots (Pahlsson 1989, Rhoads et al. 1989, Vasquez et al. 1989).

Shifts in the composition of the plant community in response to contaminants have not been widely documented. Relevant studies include:

- Arsenic, cadmium, copper, lead, and zinc inhibited growth in hybrid poplar (*Populus*) and several other tree species (Lejeune et al. 1996).
- Iron and manganese, although not usually toxic to wetland plants, do affect species in some wetland types. For example, laboratory experiments revealed differences among 44 fen species with regard to the influence of iron on growth (Snowden and Wheeler 1993).
- Oil spills can have long-lasting effects on wetland plant communities (Obot et al. 1992). In a greenhouse experiment, oil and a detergent used to clean up oil spills were applied to broadleaf arrowhead (*Sagittaria lancifolia),* salt marsh sedge (*Scirpus olneyi),* and common cattail (*Typha latifolia).* The leaves on all of the study plants died following oiling, but new leaves soon developed on those plants subjected to oil and subsequent cleaning with the detergent. *S. olneyi* was the least sensitive of the three species, whereas *T. latifolia* appeared to be the most sensitive (Pezeshki et al. 1998).
- The herbicides Rodeo® and Garlan 3A®, applied to control purple loosestrife (*Lythrum salicaria*), also reduced the growth rates of non-target species such as duckweed (*Lemna gibba)* (Gardner and Grue 1996).

4.8.4 Impacts on Invertebrates from Toxic Contaminants in the Habitat

General studies on the impacts to invertebrates in wetlands of Puget Sound found that increased levels of contaminants and changes in the water regime correlated with declines in species richness among the scraper and shredder functional feeding groups and the Chironomidae family (small, mosquito-like flies) (Ludwa 1994). These authors found declines in richness and abundance of invertebrate groups whose presence is seen as an indicator of the general health or quality of a water body. Another study in Massachusetts also showed a direct and negative correlation between urbanization and the abundance and richness of macro-invertebrates (Hicks 1995) primarily through impacts to water quality.

The following sections first review the effects of metals on invertebrates and then describe the effects of organic and synthetic compounds such as pesticides. Much of the information on the impacts on invertebrates is based on studies in streams. These studies are probably applicable to wetlands because some of the species and many of the invertebrate families reported in the studies are also found in wetlands.

4.8.4.1 Impacts of Heavy Metals on Invertebrates

Heavy metals such as mercury, lead, zinc, copper, and cadmium can be directly toxic to wetland invertebrates. Metals can also impact invertebrate communities by altering the species composition and abundance of algae and aquatic plants upon which invertebrates

depend for food and shelter. Growth, larval development, and reproduction of invertebrates can also be harmed by long-term exposure to sublethal concentrations of trace metals (Timmermans 1993). Relatively little, however, is known about the sublethal effects of metal pollutants in freshwater wetlands or how metals are metabolized or accumulated.

The extent to which heavy metals are toxic to wetland invertebrates depends largely on the acidity of the wetland and the particular form of the metal involved. Acidic conditions can mobilize and increase the toxicity of some metals, such as cadmium (Wright and Welbourn 1994), and decrease the toxicity of others, such as aluminum (Wren and Stephenson 1991). On the other hand, some metals, such as iron and aluminum, can to some degree protect invertebrates from otherwise toxic effects of heavy metals in acid mine drainage (Whipple and Dunson 1992).

Specific studies documenting the impact of heavy metals on invertebrates are summarized below:

- Moderate recovery of invertebrates from metal contamination was demonstrated in the Coeur D'Alene River in Idaho. Over 22 years after contamination by zinc and other metals ceased, the number of species grew from zero to 18, while the proportion of mayflies, stoneflies, and caddisflies relative to the proportion of midges rose (Hoiland and Rabe 1992, Hoiland et al. 1994).
- Some studies show herbivores and detritivores as the most sensitive to additions of metals (Kiffney and Clements 1994a, Leland et al. 1989), whereas others have reported scrapers being the most sensitive group (Clements 1994).
- Mayflies and some stoneflies of western streams are sensitive to metals, whereas caddisflies and midges are relatively tolerant (Clements 1994, Kiffney and Clements 1994b, Leland et al. 1989).
- Agricultural drainage water containing arsenic, boron, lithium, and molybdenum entering the Stillwater Wildlife Management Area in Nevada proved acutely toxic to many wetland invertebrates (Hallock and Hallock 1993).
- Copper and some other heavy metals appear to be more damaging to aquatic communities in the spring and summer rather than in the fall (Leland et al. 1989). Summer exposure to metals may coincide more closely with hatching of many macro-invertebrates, and early periods in the development of the invertebrates may be more susceptible.

4.8.4.2 Impacts of Pesticides, Oil, and Other Contaminants on Invertebrates

Pesticides, oil, and other toxic contaminants represent a wide range of pollutants. In general, however, most have been shown to change the community structure (abundance, distribution, and richness) of invertebrates. Contaminants cause these effects through several mechanisms, including:

- Causing acute or chronic toxicity to invertebrates
- Altering algal communities and aquatic plants upon which some invertebrates depend for food and shelter
- Altering predation on invertebrates by decimating numbers of other crustaceans, fish, and amphibians
- Reducing rates of oxygen diffusion
- Changing the effects of other potential disturbances, such as acidity

The range of pesticides and organic pollutants used today is very large and it is not possible to generalize the impacts of this group of pollutants on invertebrates. Table 4-1 summarizes numerous studies that demonstrate the wide range of responses of invertebrates to contaminants.

Table 4-1. Summary of studies on effects of contaminants on invertebrates.

Reference	Contaminant Studied	Results
Eisler (1992)	diflubenzuron (insecticide)	In laboratory tests diflubenzuron was most toxic to crustaceans, followed by mayflies, midges, caddisflies. Larvae of corixids, dragonfly adults and larvae, spiders, dytiscids, and ostracods had moderate sensitivity
Eisler (1992)	paraquat, cyanide, fenvalerate, acrolein	These substances were lethal to invertebrates
Dieter et al. (1996)	phorate (pesticide)	In Prairie Pothole Region, macro-invertebrates that were particularly sensitive to phorate included hemipterans, mosquitoes, flies, mayflies, water mites, and water beetles. Less sensitive were leeches, snails, aquatic worms, ostracods
Lieffers (1990)	3-trifluoromethyl-4-nitrophenol (TFM) (lampricide)	TFM had a significant effect on invertebrates in a small stream
Fairchild and Eidt (1993)	fenithrothion (insecticide for forest insects)	Fenithrothion reduced emergence of aquatic insects for 6 to 12 weeks. Densities of most invertebrates (especially predatory species, midges, some other dipterans) were reduced by as much as 50% for more than one month after treatment. Wetland sediments became dominated by aquatic worms and water mites. Although in many streams and large lakes fenithrothion has transitory effects, residual toxicity remained in bog wetlands during winter and into the next year
Hachmoller et al. (1991)	various organic pollutants	Mayflies, stoneflies, caddisflies decreased in abundance in stream contaminated by various organic pollutants

Reference	Contaminant Studied	Results
Keller (1993), Metcalfe and Charlton (1990)	various contaminants	Mussels are especially sensitive to combined effects of pesticides, organic compounds, excessive nutrients
Kemp and Spotila (1996)	industrial pollutants, PCBs	Isopods, oligochaetes, craneflies were main survivors in a Pennsylvania stream with industrial pollution (including PCBs) compared with non-urbanized control segments
Crunkilton and Duchrow (1990)	oil	After 25 days, an oil spill in a Missouri stream reduced macro-invertebrate population to less than 0.1% of normal densities. Recovery of some species of stoneflies, mayflies, and caddisflies did not occur for at least nine months
Henry et al. (1994)	surfactant	In laboratory tests, a surfactant was approximately 100 times more toxic than the herbicide glyphosate, with which it is commonly applied
Wipfli and Merritt (1994), Kreutzweiser et al. (1994), Jackson et al. (1994), Waalwijk et al. (1992)	*Bacillus thuringiensis* var. *israelensis* (Bti) (biological control agent)	Bti appears to have minimal adverse effects on non-target insects in streams although mortality has been observed in Lepidoptera, some midges, craneflies, caddisflies, mayflies
Euliss and Mushet (1999)	agricultural contaminants	Direct adverse correlation found between aquatic invertebrate species richness and agricultural practices for seasonally inundated wetlands in prairie pothole region of North Dakota. Adverse effects on invertebrates could result from agrichemicals (shown to cause increased mortality of aquatic invertebrates in other studies). Tilling around wetlands could increase erosion, leading to suspended sediments and adsorbed metals that are toxic to some zooplankton and thus affect the food chain

4.8.5 Impacts on Amphibians and Reptiles from Toxic Contaminants in the Habitat

Studies of the effects of heavy metals, pesticides, and other toxins on amphibians and reptiles have been conducted mainly on species, not communities. A review of relevant literature was published by Sparling et al. (2000). Schuytema and Nebeker (1996) have compiled a database of toxicity information from published literature for 58 amphibian species as related to 135 chemicals.

Many different pollutants have been documented as toxic to species of amphibians and reptiles found in Washington's wetlands. The following references document the impact of toxic compounds on some species found in the Pacific Northwest:

- Toxic effects of aluminum and other metals on the embryos and tadpoles of the northern leopard frog (*Rana pipiens*) were found by Freda (1991), Freda and McDonald (1990), and Freda et al. (1990).

- Many synthetic organic compounds affect amphibians and aquatic reptiles. Northwestern salamander (*Ambystoma gracile*) egg mortality corresponded with levels of total petroleum hydrocarbons in western Washington (Platin 1994, Platin and Richter 1995).

- The pesticide esfenvalerate caused damaging sublethal effects on tadpoles of the northern leopard frog (Materna et al. 1995).

- Tests of three forest insecticides (fenitrothion, triclopyr, and hexazinone) on the northern leopard frog in Ontario suggested that tadpoles were sensitive to triclopyr and fenitrothion (Berrill et al. 1991).

4.8.6 Impacts on Fish from Toxic Contaminants in the Habitat

The response of fish communities and individual species to toxic compounds is varied and complicated by many environmental factors. Smaller fish may be the first to respond to contaminants (Matuszek et al. 1990).

The toxicity of copper and zinc to some fish species depends on other chemical characteristics of the water (Munkittrick and Dixon 1992, Welsh et al. 1993), as well as fish behavior (Pourang 1995). For example, dissolved organic matter from a marsh at a level of 5 mg carbon per liter kept copper from binding to the gills of small steelhead (*Oncorhynchus mykiss*), thereby reducing its toxicity. This occurred because copper formed a complex with dissolved organic carbon, making the copper unavailable (Hollis et al. 1997). In addition, some fish species may acclimate to moderately elevated levels of some metals (Klerks and Lentz 1998).

Selenium is not directly toxic to fish at concentrations usually found in soils but can become toxic once concentrated in fish food chains. This is especially true in some wetlands that receive effluents from irrigated fields or power plant reservoirs in some regions (Zilberman 1991, Lemly 1996).

Synthetic organics, including pesticides, can accumulate in wetland fish (Cooper 1993), often with adverse effects. In a Canadian wetland receiving effluent containing oily sand, fish had altered blood chemistry and died within fourteen days (Bendell-Young et al. 2000).

4.8.7 Impacts on Birds from Toxic Contaminants in the Habitat

The response of individual bird species and bird communities to toxic compounds is varied. Individual species are directly affected by many pollutants. Many pesticides, however, are more likely to impact bird populations by altering their habitat and foods rather than by direct toxicity. Studies that document such impacts are summarized below:

- Several instances have been documented of wetland birds being directly poisoned by insecticides applied at recommended rates (e.g., parathion, as documented by Flickinger et al. 1991).

- Herbicides have been applied to wetlands to change the structure of vegetation and the composition of plant species, with consequent shifts in the composition of bird species (Solberg and Higgins 1993, Linz et al. 1996). Information on pesticides in prairie wetlands has been compiled by Facemire (1992).

- Detrimental reproductive effects from dioxins have been documented for great blue herons (*Ardea herodias*) (Hart et al. 1991); for dioxins and furans for wood ducks (*Aix sponsa*) (White and Seginack 1994); for PCBs (polychlorinated biphenyls) in American kestrels (*Falco sparverius*); and for petroleum in mallards (*Anas platyrhynchos*) (Holmes and Cavannaugh 1990).

- Research has continued to focus on the effects of selenium on waterfowl in western states. Biogeochemical conditions favoring the release of selenium into wetlands are found throughout the arid regions of the western states and threaten bird communities in many wetlands along the Pacific and Central Flyways (Paveglio et al. 1992). Agricultural drainage, irrigation, and natural waters can leach selenium from many western soils. Subsurface irrigation is the most widespread and biologically important source of selenium toxicity for waterfowl, including the waterfowl in six national refuges (Ohlendorf et al. 1990, Feltz et al. 1991). Selenium is often accompanied by boron, which is toxic to ducklings (Stanley et al. 1996).

Lead shot as a source of toxic metal

The use of lead shot for hunting is banned in Washington State but its use is still allowed for target shooting. If target ranges are adjacent to wetlands the potential exists of lead entering these wetlands. The pathways for uptake of lead shot by aquatic birds would be the same whether the source is from active hunting or from target shooting.

Lead is toxic to aquatic biota (Eisler 1988). Waterborne lead is the most toxic form. The introduction of lead into the aquatic food chain via aquatic plants has been found in the roots and foliage of the pond weed *Potamogeton foliosus* and in the exoskeleton of crayfish (Eisler 1988, Knowlton et al. 1983). Elemental lead (lead shot), however, has been shown to be significantly less bioavailable to rooted aquatics than powdered lead (Behan et al. 1979).

Waterfowl are at risk from ingesting lead shot as they forage in wetlands. Because of the proximity of wetlands to shooting ranges, other aquatic organisms, including amphibians, and some bird species may be at risk from the spent lead. For example, Eisler (1988) found that lead in tadpoles might contribute to the lead levels reported in wildlife that eats tadpoles. Predatory animals that feed on amphibians include reptiles (such as the garter snake), birds such as the great blue heron and the marsh hawk, and mammals such as raccoons (Martin et al. 1951).

4.8.8 Impacts on Mammals from Toxic Contaminants in the Habitat

No explicit information was found in the literature on the possible impacts of toxicity from contaminants in wetlands on mammals using wetlands. It is not possible at this stage to hypothesize either positive or negative impacts on mammals because no logical deductions could be made from the available information.

4.8.9 Summary of Key Points

- No information was found on the impacts of contaminants on the hydrologic functions of wetlands, but it can be hypothesized that increases in sediment can reduce the storage of water in depressional wetlands.
- The rates at which wetlands remove toxic compounds may actually be increased under low levels of contamination because the specific microbes that detoxify the pollutants are stimulated.
- The impact of contaminants on plants has not been studied as extensively, but the information suggests that toxicity from contaminants can change the composition of the plant community.
- Impacts of increased contaminants on the habitat provided by wetlands have been documented for invertebrates, amphibians, fish, and birds. Many contaminants are toxic to these species and their presence in wetlands reduces the suitability of a wetland as habitat. Wetland-associated mammals are the only group of vertebrates for which no information was found.

4.9 Impacts from Changing the Acidity (pH) of Soils or Water in a Wetland

4.9.1 Impacts on Hydrologic Functions from Changing the Acidity

No information was found on the impacts that increasing acidity might have on the hydrologic functions performed by wetlands. In the absence of any information to the contrary, however, it is possible to hypothesize that decreasing pH will probably not change how wetlands perform these functions. Changes in the acidity of water are not expected to change how well wetlands store water, how well they slow it down during peak flows, or how well they recharge groundwater.

4.9.2 Impacts on Functions that Improve Water Quality from Changing the Acidity

Increased acidity (reduced pH) could change aspects of wetland chemistry that affect the ability to improve water quality. It can be hypothesized that the rate of nitrification will probably decrease because, as noted by Mitch and Gosselink (2000), low pH inhibits denitrifying bacteria. Changes in pH will also change the ability of the wetland to bind different toxic metals and other contaminants in the soils (Kadlec and Knight 1996). Each contaminant, however, has different chemical properties. Some are released when pH decreases (acidity increases) and some are more tightly bound when pH decreases. The impacts of changing the pH, will, therefore, depend on the contaminants coming into the wetland.

4.9.3 Impacts on Plants from Changing the Acidity

The pH is critical in determining the distribution of plants in wetlands. Changes in pH that result from human activities can, therefore, have major impacts. Studies described below have documented changes in plant populations that resulted from both decreases in pH (more acidic conditions) and increases in pH (less acidic conditions). However, the effects of acidification (or its reversal by liming) on the species composition of plants are not consistent among wetland types or even within individual wetlands (Farmer 1990, Baker and Christensen 1990, Mackun et al. 1994, Weiher et al. 1994).

For example, many plant species that inhabit bogs are adapted to acidity levels that would kill most wetland plants. Species whose decline or disappearance from a lacustrine wetland coincided with acidification include water lobelia (*Lobelia dortmanna)*, shore quillwort (*Isoetes riparia*), water milfoil (*Myriophyllum tenellum)*, yellow pond lily (*Nuphar* sp.), common bladderwort (*Utricularia vulgaris)*, and ribbon leaf pondweed (*Potamogeton epihydris)* (Farmer 1990). Species whose relative abundance increased included *Leptodictium riparium*, needle spike rush (*Eleocharis acicularis)*, sphagnum moss *(Sphagnum* sp.), and pipe wort (*Eriocaulon septangulare)* (Farmer 1990).

In general, making wetlands more acidic can directly impact plants by limiting the availability of some inorganic nutrients and carbon (Farmer 1990). Acidic conditions also promote the conversion of nitrates into ammonium.

Acidic conditions can impact plants indirectly by reducing the densities of invertebrates that graze or process detritus. Acidic conditions in wetland soils increase the toxicity of aluminum and manganese (Rendig and Taylor 1989, Crowder and Painter 1991).

4.9.4 Impacts on Invertebrates from Changing Acidity in the Habitat

In general, changing the acidity in a wetland can alter the community structure of invertebrates by:

- Causing acute or chronic damage to tissues of invertebrates; the species that easily lose sodium ions when pH is reduced tend to be most sensitive (Steinberg and Wright 1992)

- Altering algal communities and aquatic plants upon which some invertebrates depend for food and shelter (see discussion in Section 4.9.3)

- Altering the populations that are predators of invertebrates such as other crustaceans, amphibian, and fish (see Sections 4.9.5, 4.9.6)

The impacts of acidification on aquatic invertebrate communities have been researched extensively. Table 4-2 categorizes invertebrate species as more or less tolerant of acidification based mainly on the North American literature. The list is included here because many of these species are probably found in Washington's wetlands. Few local studies, however, document the distribution of invertebrates in the state so it is not possible to identify the tolerance of species that are found here.

Some invertebrates are sensitive to pH increases (decreased acidity). For example, stormwater input to a Florida freshwater marsh increased phosphorus levels, lowered oxygen levels, and raised pH and hardness. This resulted in a shift of the macro-invertebrate population toward species that otherwise are intolerant of the acidic, nutrient-poor conditions typically found in the studied wetland (Graves et al. 1998).

Acidity often reduces the richness of macro-invertebrates in aquatic habitats (Schell and Kerekes 1989, Hall 1994). One study showed that with increased acidity, many aquatic invertebrates declined in numbers and biomass, especially in wetlands with pH below 5.0 (Parker and Wright 1992). Reductions in acid emissions from some Canadian smelters were followed by significant increases in richness of invertebrates in water bodies downwind of the smelters (Griffiths and Keller 1992).

Table 4-2. Summary of studies describing relative tolerance of invertebrates to acidification.

Taxonomic Group and Study Reference	More Tolerant to low pH (Less Sensitive)	Less Tolerant to low pH (More Sensitive)
Dragonflies and Damselflies (Odonata)		
Damselflies (Parker and Wright 1992, Baker and Christensen 1990)	X	
Beetles (Coleoptera)		
Some water beetles (Parker and Wright 1992), especially hydrophilid and dystiscid beetles (Baker and Christensen 1990)	X	
True Bugs (Hemiptera, Homoptera)		
Some water bugs, at least Notonectidae, Gerridae, Corixidae (Baker and Christensen 1990)	X	
Some water bugs (Parker and Wright 1992)		X

Taxonomic Group and Study Reference	More Tolerant to low pH (Less Sensitive)	Less Tolerant to low pH (More Sensitive)
Caddisflies (Trichoptera)		
Some caddisflies: *Cheumatopsyche pettiti* (Camargo and Ward 1992).	X	
Some caddisflies (Parker and Wright 1992) and some in the scraper and predator guilds (Williams 1991)		X
Flies, Midges, Mosquitoes (Diptera)		
Midges (Havens 1994a, Baker and Christensen 1990, Tuchman 1993)	X	
Some midges, such as *Tanytarsus, Microtendipes*, and *Nilothauma* (Griffiths and Keller 1992)		X
Stoneflies (Plecoptera)		
Some stoneflies (Tuchman 1993) such as *Amphinemura* and *Leuctra* (Griffith et al. 1995)	X	
Many stoneflies, e.g., *Peltoperla arcuata* (Griffith et al. 1995)		X
Mayflies (Ephemeroptera)		
The mayfly *Eurylophella funeralis* (Griffith et al. 1995)	X	
Some mayflies (Balding 1992)		X
Other Macro-invertebrates		
Planarian *Dugesia dorotocephala* (Camargo and Ward 1992)		X
Some water mites (Havens 1994a)	X	
Molluscs (Grapentine and Rosenberg 1992, Gibbons and Mackie 1991, Balding 1992), including clams (Schell and Kerekes 1989)		X
Mussels, snails, leeches (pH >5.0, Schell and Kerekes 1989)		X
The amphipod *Hyalella azteca* (Havens 1994a); pH must remain above 5.8 (Grapentine and Rosenberg 1992)		X
The amphipod *Gammarus minus* (Griffith et al. 1995)		X
Zooplankton		
Some zooplankters, such as *Daphnia galeata mendotae, D. retrocurva, Skistodiaptomus oregonensis* (Havens 1993)	X	
The rotifers *Gastropus stylifer, Keratella taurocephala, Polyarthra renata, Symchaeta* sp. (Fore et al. 1996)	X	
The water flea *Bosmina longirostris* (Havens 1993)		X

Taxonomic Group and Study Reference	More Tolerant to low pH (Less Sensitive)	Less Tolerant to low pH (More Sensitive)
The rotifers *Asplanchna priodonta, Collotheca mutabilis, Conochiloides* sp., *Conochilus unicornis, Gastropus hyptopus, Kellicota longispina, Keratella cochlearis, Keratella crassa, Polyarthra dolichoptera, Trichocera cylindrica* (Fore et al. 1996)		X
Functional Feeding Groups		
Scrapers and collectors (Smith et al. 1990)	X	
Shredders (Tuchman 1993)		X
Deposit feeders (Smith et al. 1990)		X

4.9.5 Impacts on Amphibians and Reptiles from Changing the Acidity in the Habitat

Increased acidity (lower pH) damages amphibians directly (Horne and Dunson 1994b). Acidity may also have direct impacts as a result of its capacity to mobilize toxic metals and perhaps by making sodium less available in some soil types (Wyman and Jancola 1991).

No studies were found describing the impact of increased acidity on amphibians and reptiles in Washington. Studies from other states, however, document these impacts. The information below summarizes some of the information for amphibian and reptile species that are found in the state, even if the studies were done elsewhere.

In Ontario, the acid-neutralizing capacity (alkalinity) of 38 wetlands positively influenced the probability of the northern leopard frog (*Rana pipiens*) being present (Glooschenko et al. 1992).

Embryos of the tiger salamander (*Ambystoma tigrinum*) had more than 70% survival at pH 4.5 and above but suffered much greater mortality at lower pH levels (Whiteman et al. 1995).

Concerns have been raised regarding the vulnerability to acidification of Montane wetlands in the West. Acidification makes aluminum and cadmium more mobile and increases their concentration in surface waters. Amphibians (e.g., Jefferson's and spotted salamanders) are known to be sensitive to acidity and elevated concentrations of aluminum found in some acidic ponds (Blancher 1991, Ireland 1991, Horne and Dunson 1995).

Aluminum released into Montane pools as a result of acidification sometimes has harmed embryos, reduced growth rates, and/or caused deformities and premature hatching of native amphibians (Bradford et al. 1991, Corn and Vertucci 1992).

4.9.6 Impacts on Fish from Changing the Acidity in the Habitat

No information was found on the impacts of acidity on fish in Washington's wetlands. In their review of the literature, Adamus et al. (2001) found that acidity can be directly toxic to fish, inhibit reproductive maturation, inhibit spawning behavior, induce emigration, and alter food availability. Furthermore, in areas where acid rain may be a problem, the increase in acidity induces aluminum toxicity in fish in many lakes and wetlands (Keller and Crisman 1990). Surveys of literature on effects of acidification on fish in lakes (and therefore potentially in wetlands along lake fringes) are provided by Baker and Christensen (1990) and Minns et al. (1990).

4.9.7 Impacts on Birds from Changing the Acidity in the Habitat

Acidification of wetlands affects birds primarily because it reduces the availability of calcium, which is important for egg development; potentially increases the availability of toxic metals; and alters the species composition and abundance of aquatic insects, submersed plants, amphibians, and fish that are important foods for waterfowl (see previous discussions in Sections 4.9.3, 4.9.4, 4.9.5, 4.9.6).

Changes in the types of available food, especially those rich in calcium, can diminish egg shell thickness and generally reduce the reproductive success of waterbirds in wetlands (Sparling 1990, 1991, Blancher and McNicol 1991, St. Louis et al. 1990, Albers and Camardese 1993). Overall, calcium deficiency appears to affect birds in acidified wetlands more than metal toxicity (Albers and Camardese 1993). Breeding pairs of 15 waterfowl species were more abundant in Ontario wetlands with over 40 parts per million (ppm) of total alkalinity than in less alkaline wetlands (Dennis et al. 1989, Merendino et al. 1992). In British Columbia as well, densities of several breeding duck species were greater in ponds with higher levels of conductivity and calcium (Savard et al. 1994).

4.9.8 Impacts on Mammals from Changing the Acidity in the Habitat

No information on the effects of acidification on the overall community structure of wetland mammals was located. It can be hypothesized, however, that where acidification becomes severe, community composition may shift from fish-eating species (e.g., otter) to vegetarian or invertebrate-eating species and opportunists (e.g., muskrat) (Adamus and Brandt 1990).

4.9.9 Summary of Key Points

- No information was found on the impacts of acidity on the hydrologic functions of wetlands, but it is possible to hypothesize that impacts, if any, are minor.
- The rates at which wetlands remove nitrogen are impacted by increasing acidity because denitrification is reduced.
- The rates at which toxic metals and other contaminants are removed by soils can change with acidity, but the actual changes depend on the chemical properties of the contaminant.
- Increasing the acidity in wetlands can also change the composition of the plant community.
- Impacts of increasing acidity on the habitat provided by wetlands have been documented for invertebrates, amphibians, fish, and birds. In general, increased acidity reduces the richness of invertebrates in wetlands and impacts amphibians either directly or by changing the chemistry of the water in the wetland, making it less suitable as a habitat. Acidic wetlands also become a less suitable habitat for birds because the amounts of calcium rich foods are reduced. Mammals are the only group of vertebrates for which no information exists.

4.10 Impacts from Increasing the Concentrations of Salt in a Wetland

Salt concentration in wetlands can increase as a result of (from Adamus et al. 2001):

- Isolating wetlands from some types of groundwater inflow
- Increasing water lost through evaporation
- Discharging effluents that contain salts (especially irrigation return water)
- Routing runoff that has relatively high conductivity into wetlands

Increased concentrations of salt (salinization) impact the functions of wetlands as described below.

4.10.1 Impacts on Hydrologic Functions from Increasing Concentrations of Salt

No information was found on how changes in salt content might affect the hydrologic functions of flood storage and flood desynchronization [the process by which peak flows are

delayed in their downstream movement (Adamus et al. 1991)]. However, it is possible to hypothesize that salinization will probably not change how wetlands in Washington perform these functions. Changes in the salt content of water coming into a wetland are not expected to change the physical structure of the wetland on which the hydrologic functions are based. Increasing salt concentrations are not expected to change how well wetlands store water, how well they slow it down during peak flows, or how well they recharge groundwater.

4.10.2 Impacts on Functions that Improve Water Quality from Increasing Concentrations of Salt

One relevant study found that salinities greater than about 300 grams per liter can inhibit the ability of microbes to detoxify toxic forms of selenium (Steinberg and Oremland 1990). This was the only literature found on how salinization might impact the ability of wetlands to remove pollutants.

As noted below, salinization has some impacts on plants, and thus it may affect nutrient uptake and transformation in a wetland. However, it is not possible to predict or hypothesize how such changes in these species might change other functions that improve water quality.

4.10.3 Impacts on Plants from Increasing Concentrations of Salt

In general, high concentrations of soluble salts are lethal to freshwater plants, and lower concentrations may impair growth (Rendig and Taylor 1989). Woody plants tend to be less tolerant than herbaceous plants because they do not have mechanisms for removing salt, other than accumulating salts in leaves and subsequently dropping them (Adamus et al. 2001).

Many plant species that inhabit inland saline wetlands are, of course, adapted to tolerating salt levels that would kill most other freshwater wetland plant species. A survey of inland lakes in western Canada which spanned a salinity gradient identified relative tolerance to salinity and specific salinity tolerance thresholds of many wetland species (Hammer and Heseltine 1988).

Individual plant species have different tolerances and reactions to increasing salinity. It can be expected that the plant community in a wetland will change to one dominated by salt-tolerant plants when additional salts are introduced. For example, wetlands in which salt has been present for some time, such as alkali wetlands, have a completely different plant community than that found in non-alkali wetlands. In eastern Washington a major change in plant communities was found when the conductivity (a measure of the amount of salts present in the water) increased to 2.0 milliSiemens and higher (Hruby et al. 2000).

A study by Hutchinson (1991) describes the tolerance of many wetland plants found in Washington. It can be used to predict how the plant species might change in Washington's wetlands as salt concentrations increase.

It can also be expected that wetlands subject to increases in salinity through agricultural practices or discharges of salt will also be subject to a change in plant populations. One wetland undergoing such a change was observed in the Richland area by the technical team calibrating the Washington State wetland rating systems in the summer of 2002. The conductivity of the wetland was measured at about 6.5 milliSiemens. About one-quarter of the area was still dominated by cattails (*Typha latifolia*), a wetland plant with a relatively low tolerance to salt (Hutchinson 1991), but this species was dying. Dead stalks of this species covered almost half the area of the wetland.

4.10.4 Impacts on Invertebrates from Increasing Concentrations of Salt in the Habitat

The review of the literature indicates that high levels of salinity can alter the structure of freshwater invertebrate communities in many ways. Adamus et al. (2001) have identified the following mechanisms by which the invertebrate community can be altered:

- Acute and chronic damage to tissues of invertebrates
- Changes in the species composition and structure of algal communities and aquatic plants upon which some invertebrates depend for food and shelter
- Changes in predation on invertebrates by decimating numbers of other crustaceans, fish, and amphibians
- Changes in the bioavailability of some other substances, such as heavy metals and nutrients

Even at low concentrations, increases in chloride (a correlate of salinity, and often associated with road salt applications) among twenty-seven Minnesota wetlands were significantly correlated with declines in species richness among the wetlands (Gernes and Helgen 1999). In Wyoming wetlands of fairly low salinity (0.8 to 30 milliSiemens per centimeter), the dominant macro-invertebrates were amphipods and epiphytic snails. Other recent species-specific data on the impacts of salinity in wetland invertebrates are presented in Parker and Wright (1992), and Lovvorn et al. (1999).

4.10.5 Impacts on Amphibians and Reptiles of Increasing Concentrations from Salt in the Habitat

In general, relatively little is known about amphibian tolerance to salinity in Washington. Three studies have reported a statistically significant negative correlation between conductivity of the water and amphibian species richness (Azous 1991, Platin 1994, Platin

and Richter 1995). However, the implications of these studies for understanding impacts on existing populations of amphibians in a wetland that is undergoing an increase in salt concentrations is not clear.

4.10.6 Impacts on Fish from Increasing Concentrations of Salt in the Habitat

No information was found on the tolerance of native fishes in Washington to salinity. Adamus et al. (2001) reported the following information relative to some of the introduced game fish that now are found in Washington's wetlands.

Laboratory trials consisting of 120-day exposure of freshwater largemouth bass (*Micropterus salmoides*) to four salinity levels (0, 4, 8, and 12 ppm) indicated a significant decrease in growth rate with increasing salinity up to 8 ppm.

In another experiment, juvenile bluegill (*Lepomis macrochirus*) from a freshwater pond in northeastern Mississippi and a brackish bayou in coastal Mississippi were held in a chamber with zero salinity but given access to chambers containing 0, 2, 4, 6, 8, and 10 ppm salinity (Peterson et al. 1993). Fish from neither habitat showed a clear preference for any of the salinity options. These data and data from previous studies suggest bluegills are better able to physiologically and behaviorally tolerate elevated salinity relative to other centrarchids (the family of fish containing bluegills, bass, crappies, etc.), particularly bass (Peterson et al. 1993).

4.10.7 Impacts on Birds from Increasing Concentrations of Salt in the Habitat

The impacts of increasing salinity on birds are highly dependent on the species in question. The following summarizes relevant studies:

- Highly saline or alkali conditions are detrimental to some invertebrate and plant foods used by many duck species. High salinity is directly toxic or impairs the growth of young ducklings (Clark and Nudds 1991, Moorman et al. 1991).

- Breeding densities of most duck and grebe species in interior British Columbia were greater in ponds with higher conductivity (higher salt content), but marsh nesting species were unaffected (Savard et al. 1994).

- Some species of water birds are very tolerant of high salt concentrations. They occur regularly at very high densities in alkali wetlands during the breeding season and/or migration. Examples include the American avocet (*Recurvirostra americana*), snowy plover (*Charadrius alexandrinus*), phalaropes, killdeer (*Charadrius vociferus*), horned grebe (*Podiceps auritus*), tundra swan (*Cygnus columbianus*), and white-rumped, semipalmated, and Baird's sandpipers (*Calidris* spp.) (Jehl 1994, Savard et al. 1994, Oring and Reed 1997, Rubega and Robinson 1997, Warnock 1997).

4.10.8 Impacts on Mammals from Increasing Concentrations of Salt in the Habitat

No information was found on the impacts of salinization on the overall structure of mammal communities in wetlands and changes in the suitability of wetlands as habitat for mammals.

4.10.9 Summary of Key Points

- No information was found on the impacts of salinization on the hydrologic functions of wetlands, but it is possible to hypothesize that impacts, if any, are minor.
- Only one study was found that documents any impacts of salinization on the ability of wetlands to improve water quality. Very high salt concentrations inhibit the microbes that detoxify selenium.
- Increasing the salt concentrations in wetlands can change the composition of the plant community because specific species are more tolerant of saline conditions than others.
- Impacts of increased salt concentrations on the habitat provided by wetlands have been documented for invertebrates, fish, and birds. In general, increased salinity changes the composition of the invertebrate community in wetlands. Largemouth bass seem to be especially sensitive to increased salinity relative to other species. The young of some waterbird species may also be sensitive, but other species seem to prefer high salinities. No information exists on the impact of salinization on mammals and amphibians.

4.11 Impacts from Fragmenting Wetland Habitats

Fragmentation results directly from human conversion of land to other uses. As described in Chapter 3 fragmentation is a result of both the direct loss of wetland area that isolate populations of wildlife and from changes to the spatial configuration of the wetlands in the landscape. Wetland loss and isolation is seen as a major factor contributing to the loss of biological diversity in vertebrate populations that use wetlands (Harris 1988, Gibbs 2000).

In general, fragmentation of habitats affects biological diversity through (Harris 1988):

- Loss of the species less tolerant to disturbance or those that inhabit the interior parts of wetlands
- Loss of large species with broad ranges
- Loss of genetic integrity within populations
- Increase in numbers of habitat generalists that thrive in disturbed environments, such as parasites

Occasional migration between wetlands is vital in sustaining local populations of wetland-dependent organisms. Limiting the movements of these species reduces the exchange of genetic material among local populations and can result in population extinctions (Gibbs 2000). Three factors that impede movement among wetlands and other habitats include (Gibbs 2000):

- Greater distances between wetlands
- Degradation of upland habitats
- Increased road density

The effects of fragmentation on wildlife that use wetlands are most extensively documented for amphibians and birds. Little information is available for effects on macro-invertebrates, reptiles, and mammals. Several studies done in the Pacific Northwest are cited in the following discussion of how fragmentation impacts wetland functions.

4.11.1 Impacts on Hydrologic Functions from Fragmentation

No information was found on how fragmentation may impact the flood storage, flood desynchronization, and groundwater recharge performed by individual wetlands. It is possible, however, to hypothesize that fragmentation will probably not change how individual wetlands still remaining in the landscape perform these functions. Fragmentation at a landscape level is not expected to change how well the remaining individual wetlands store water or how well they slow it down during peak flows. On the other hand, fragmentation probably does impact the delivery and routing of water to wetlands as described in Chapter 3. This may change how much water gets to a wetland for storage but not how well the wetland can store it.

4.11.2 Impacts on Functions that Improve Water Quality from Fragmentation

No information was found on how fragmentation may impact the ability of wetlands to improve water quality. It is not possible to hypothesize precisely how such changes might affect these functions because related information was also not found.

4.11.3 Impacts on Plants from Fragmentation

The only information found on the response of wetland plant communities to fragmentation are the series of studies carried out by J. Lienert in fens of Switzerland (Lienert, Diemer and Schmid 2002; Lienert, Fischer et al. 2002; Lienert, Fischer, and Diemer 2002; Lienert and Fischer 2003). These studies on the populations of individual obligate wetland plants show that fragmentation can have the following impacts:

- Fragmentation can reduce the genetic variability in a population (Lienert, Fisher, et al. 2002)
- Fragmentation reduces the densities and size of a plant population (Lienert and Fischer 2003)
- Fragmentation reduces the viability of a plant population (Lienert, Diemer and Schmid 2002)
- Fragmentation can lead to the local extinction of a wetland species (Lienert, Fischer, and Diemer 2002)

4.11.4 Impacts on Invertebrates from Fragmentation

Few studies were found that documented the impact of decreasing connections on the suitability of wetlands as habitat for invertebrates. One study found that wetland isolation combined with the harshness of the surrounding upland landscape in more arid environments (such as much of eastern Washington) limit dispersal and colonization by aquatic invertebrates (Myers and Resh 1999).

Another study in New York comparing macro-invertebrate populations at restored wetlands and reference wetlands showed that less mobile invertebrates colonized new wetland sites very slowly or not at all, whereas insects that disperse aerially colonized the new sites rapidly (Brown et al. 1997). Therefore, wetland isolation may have greater effects on less mobile invertebrate species.

4.11.5 Impacts on Amphibians and Reptiles from Fragmentation

4.11.5.1 Amphibians

As early as the mid-1960s, researchers in various parts of the country documented the effects of fragmentation on amphibians. One author notes the disappearance of a number of species of frogs, toads, turtles, and snakes in an urbanizing area in the Midwest that he studied from 1949 to 1964 (Minton 1968).

The effects of increased wetland isolation have been extensively studied for amphibians since then. This is probably because amphibians:

- Are restricted to movement on the ground
- Do not typically have large migration ranges
- Often move between terrestrial and aquatic habitats
- Have experienced significant population declines throughout the world

The causes of declines in the populations of amphibians have been extensively studied and most researchers conclude that the problem is very complex and multiple factors are likely at work (Hayes and Jennings 1986, Pechmann et al. 1991, Pechmann and Wilbur 1994, Delis et al. 1996, Adams 1999a). Among these factors, there is evidence that increasing isolation of wetlands due to wetland loss may play a significant role in declining amphibian populations (Ostergaard 2000, Adams 1999a, Lehtinen et al. 1999, Semlitsch and Bodie 1998). This has significant implications for amphibians in Washington State because about 97% of amphibian species that occur here commonly use wetlands for at least one life cycle stage (Leonard et al. 1993).

Amphibians are not randomly distributed within acceptable habitats—they occur in higher abundance and species richness in habitats that are better connected to other desirable habitats (Lehtinen et al. 1999, Lehtinen and Galtowitsch 2001). A Minnesota study of 21 marshes noted that the two most important predictors of decreases in amphibian species richness in agricultural areas are the degree of wetland isolation and the road density (Lehtinen et al. 1999). The marshes in this study were located in both prairie and hardwood forest ecoregions in two primary land-use settings: urban and agricultural. The study noted some differences between ecoregions and land-use effects. In the agricultural prairie ecoregion, the amphibian assemblages observed appeared to be most influenced by:

- Road density
- Wetland isolation
- Biological interactions (presence of predators)

In deciduous forest areas that are urbanizing, amphibian richness was most closely related to upland land use and associated habitat fragmentation.

Other landscape-based studies also conclude that the distances between wetlands, as well as the suitability of terrestrial habitats, are key factors in amphibian distribution. Amphibian recolonization patterns are species and spatially dependent because not all species have the capacity to move beyond fragmented, isolated habitats (Lehtinen and Galatowitsch 2001).

Declines in the richness of amphibian species have also been documented as urban land use increases (Lehtinen et al. 1999, Knutson et al. 1999, Richter and Azous 2001a). A landscape analysis of habitats for anurans (frogs and toads) in Wisconsin and Iowa showed that anurans were positively associated with uplands, wetland forests, and emergent wetlands and negatively associated with urban land (Knutson et al. 1999). A positive association, in this study, means higher abundance and species richness. The negative association with urban land is attributed by the authors to:

- Conversion of habitat
- Roads acting as barriers
- Presence of exotic predators
- Chemical contamination
- Other factors

A study of the distribution of frogs in the Netherlands found that the likelihood of a pond being used by frogs depended on the density of ponds and the amount of suitable terrestrial habitat in the surrounding area (Vos and Stumpel 1995). A similar study in the Netherlands showed that frog use of ponds was negatively correlated with the degree of wetland isolation and road density in the surrounding landscape (Vos and Chardon 1998). Distances between breeding ponds and other life stage habitats, as well as the condition of the terrestrial habitats, were primary factors in determining frog distribution. Open fields were avoided by adults and newly metamorphosed juveniles. Roads increased the mortality of frogs and acted as barriers between wetlands, thus effectively increasing wetland isolation (Vos and Chardon 1998).

Similarly, an Indiana study concluded that amphibian distribution was influenced by (Kolozsvary and Swihart 1999):

- Forest area and proximity
- Density of ponds
- Duration of ponding
- Density of vegetation

The importance of each factor varied for each species.

Using a simulation model, one author concluded that the amount of breeding habitat had a significantly greater effect on the likelihood of population extinction than the extent of habitat fragmentation (Fahrig 1997). Her model showed that if breeding habitat covers more than 20% of the landscape, population extinction is very unlikely no matter how fragmented the habitat. However, this work was based on a generalized model that made a number of assumptions that cannot be verified without targeting a selected species, as do the more empirical studies of amphibian distribution.

Other studies indicate that there is a threshold for wetland isolation or distance between wetlands for the movement of each amphibian species. Several studies of maximum distances of amphibian movement to breeding habitats indicate that amphibian reproductive success is affected by wetland isolation and terrestrial habitat condition:

- Richter and Azous (1995) suggest that upland forest habitat must lie within 3,280 feet (1,000 m) of breeding wetland habitat for it to be useful to lentic (pond) breeding amphibian species in the Pacific Northwest.
- Baker and Halliday (1999) found limits on the distance that species of newts, frogs, and toads would move to colonize new ponds in England (1,312 feet [400 m] for newts, 3,117 feet [950 m] for frogs and toads). The authors also found that, in contrast to other studies, the condition and nature of the adjacent upland habitats did not have a strong correlation to pond colonization. The study may not have been sensitive enough, or the mixed land uses within the agricultural settings may have actually supported amphibian populations.

- The ability of juveniles to move from one wetland to the next depends on the spacing between wetlands and the habitat conditions within the buffers. Distances between ponds directly affect the probability of recolonization and the chance to prevent extinction of amphibian populations. Most individual amphibians cannot migrate long distances and adults return to their home ponds, usually after migrating no more than 656 to 984 feet (200 to 300 m) (Semlitsch 2000).

- A similar study in the Netherlands showed that amphibians would colonize new ponds up to 3,280 feet (1,000 m) away (Laan and Verboom 1990). The authors concluded, however, that the probability of a species colonizing a wetland increases with proximity to the source wetland and increased connectivity by upland forest habitats between the wetlands.

4.11.5.2 Reptiles

No studies were found that specifically addressed the effects of fragmentation on reptiles. In one study in North Carolina, researchers evaluated the adequacy of federal and state wetland regulations in protecting the habitats that freshwater turtles need to complete their life cycles (Burke and Gibbons 1995). They determined that the area protected as wetland under federal guidelines did not include the area in which two critical life-cycle stages occurred: nesting and terrestrial hibernation. This means that some of the habitats needed for turtle success are vulnerable to loss due to conversion to other land uses. However, this study focused not on the effects of wetland loss but the effects of eliminating upland habitats adjacent to wetlands.

A study that modeled the effects of wetland loss in Maine showed that local populations of freshwater turtles faced a statistically significant risk of extinction following the loss of small wetlands (Gibbs 1993).

As with amphibians, the limited dispersal distances of reptiles, in comparison to birds and mammals, would logically make reptiles particularly vulnerable to habitat fragmentation. However, documentation of the effects of habitat fragmentation on reptiles that use wetlands is very sparse, and it appears to be completely lacking for Washington State. With the exception of the western pond turtle (*Clemmys marmorata*) and the painted turtle (*Chrysemys picta*), no reptile species in Washington are primarily dependent on aquatic habitats. The terrestrial western and common garter snakes (*Thamnophis* spp.), however, are both common near water bodies, including wetlands.

4.11.6 Impacts on Fish from Fragmentation

No information was found on the impacts of fragmentation on the suitability of wetlands as habitat for fish. Also, not enough related information was found to make any hypotheses.

4.11.7 Impacts on Birds from Fragmentation

The impacts of fragmentation have generally been studied in two types of fragmented landscapes: one fragmented by growing urbanization and one fragmented by agricultural practices. In general there are no studies or conclusions in the literature that would suggest the fragmentation from these two types of land use has significantly different impacts on populations of birds, and so both types of studies are reported below.

The extent of wetland isolation is known to be an important factor that influences bird use of wetland habitats:

- In a study of Puget Sound wetlands, researchers documented a positive association between bird species richness and the proximity of lakes and open water habitats, as well as the structural complexity of the vegetation in the wetlands (Richter and Azous 2001b). This implies that fragmentation results in a reduction in species richness.
- In northern prairie marshes, bird species richness declined with increased isolation of the wetland (Brown and Dinsmore 1986). Marshes that were part of wetland complexes showed higher species richness than isolated wetlands. Smaller marshes had occurrences of certain bird species only when the marshes were part of a wetland complex.
- These findings are supported by a more recent study of wetland complexes in prairie marshes in Iowa (Fairbairn and Dinsmore 2001). This study related bird species richness and densities of individual species to habitat variables within the wetland complexes and to area of wetland habitat in the surrounding landscape. For some bird species, presence and abundance in a wetland complex were clearly related to the amount of wetland habitat in a 1.9 mile (3 km) area surrounding the complex. A similar study also determined that unfragmented landscapes with prairie marsh supported more waterfowl species than isolated wetlands (Naugle et al. 2001).

The pattern of habitat use in, and around, wetlands varies between different bird species that depend on wetlands (Naugle et al. 1999):

- Some species are sedentary and rarely use resources beyond the nest vicinity
- Some use only larger wetlands regardless of the surrounding landscape
- Others require a mosaic of wetlands on the landscape

Therefore, the entire landscape must be assessed, rather than just individual wetlands in order to determine the habitat suitability of an area for many species.

A correlation has been found between the degree of urban development in an area (and the resultant fragmentation) and the extent of declines in native bird species richness. One study in Santa Clara County, California, looked at six sites representing a gradient of development ranging from biological preserve to business district (Blair 1996). Increasing proportions of invasive and exotic bird species were found in the more highly developed areas. The moderately developed sites were highest in species richness and bird biomass. They were, however, lower in native bird diversity than the lesser disturbed sites. The shift in species

was related to changes in total available habitat and in habitat structure across the gradient. This study concluded that even relatively minor habitat alterations resulted in loss of species.

Wetlands in the Puget Sound area showed a similar response to urbanization. Researchers found no correlation between total bird species richness and amount of impervious surface, but there was a correlation with native species richness (Richter and Azous 2001b). The rarer, more sensitive birds, all of which are native, tended to decrease with urbanization. The more adaptive species, including a higher percentage of non-natives (e.g., European starlings [*Sturnus vulgaris*]), tended to increase in urbanizing watersheds. Again, these changes are most likely due to loss of habitat, and therefore reduced connections between habitats, as well as habitat degradation.

One study conducted in eastern Canada examined the role that habitat heterogeneity plays in the use of wetlands by ducks (Patterson 1976). It concluded that breeding duck pairs spaced themselves based on the physical size of the wetland. The authors also observed that breeding can occur in relatively less productive wetlands. However, duck broods hatched in less productive wetlands often moved to more biologically productive wetlands where there was a greater food source and more refuge/escape habitat. These preferable wetlands were close to the breeding wetlands because young waterfowl cannot fly. This would suggest that heterogeneity in the types of wetlands in an area are important in maintaining populations of ducks.

As with amphibians, the presence of terrestrial habitats between wetlands can be an important factor in waterfowl distribution. A study conducted in an area of intensive wheat farming demonstrates the importance of maintaining connections among habitats for birds (Saunders and DeRebeira 1991). These researchers found that native bird species used corridors as narrow as 13 feet (4 m) to move between patches of preferred habitat. Corridor width was positively correlated with species richness.

A study of bird populations in forest interiors found that habitat fragmentation impairs reproduction and can result in population declines and extinctions (Temple and Cary 1988). Though not focused on wetlands, the study can reasonably be applied to forested wetlands. The authors modeled the effects of habitat fragmentation. They predicted that success rates for nests for forest-interior birds would drop from 70% when nests are greater than 656 feet (200 m) from the forest edge, to only 18% when nests are less than 328 feet (100 m) from the edge. This indicates that fragmentation of forested wetlands through such activities as logging could have significant effects on species that are not tolerant of edge habitats.

In Minnesota, Mensing et al. (1998) assessed the implications of fragmentation at various landscape scales for birds. They found that:

- Diversity and richness of bird species increased with an increase in the extent of forest and wetland within the surrounding landscape.
- Habitats that were in good condition in the areas surrounding wetlands strongly influenced the biotic diversity, with positive correlations shown for birds within 1,640 feet (500 m) of the wetland edge.

4.11.8 Impacts on Mammals from Fragmentation

Information on the effects of fragmentation on mammals that depend on wetlands is sparse, even though many of the mammal species in Washington State are known to commonly use wetlands (beaver, muskrat, mink, otter, water vole, deer mouse, and others). Most of the literature on mammals in wetlands addresses the effects of beaver dams on wetland systems.

One study from the Pacific Northwest documented that fragmentation of wetlands and the elimination of surrounding upland habitats can have significant effects on small mammals that use wetlands (many of which are not, however, closely associated with wetlands). Richter and Azous (2001c) found that the total area of undeveloped land adjacent to a wetland (including forest, shrub, agricultural fields, and meadows) was weakly associated with mammal richness. A stronger correlation, however, was found between the percent of adjacent forest land (within 1,640 feet [500 m] of a wetland) and mammal richness. The highest small-mammal richness was observed in wetlands with at least 60% of the first 1,640 feet (500 m) surrounding the wetland in forest. The authors noted that richness of mammal species in Puget Sound wetlands has no correlation with area of impervious surface in the watershed.

Roads are an important factor in habitat fragmentation for mammals. For example, a major highway in Massachusetts increased wetland isolation and blocked major travel corridors between suitable habitat patches for mammals (Forman 1998). See Section 4.12.2 for additional discussion of effects of roads on wildlife.

4.11.9 Summary of Key Points

- No information was found on the impacts of fragmentation on the hydrologic functions or the functions that improve water quality.
- Increased isolation of wetlands appears to be a major factor in reducing species richness and abundance for most taxonomic groups. One author states that "modifications to the environment that preclude movement between component subsystems may be as devastating to vertebrates in the long run as are forces that actually destroy the wetland" (Harris 1988).
- Impacts of fragmentation on the habitat provided by wetlands have been documented for plants, invertebrates, amphibians, reptiles, birds, and mammals. No information was found on impacts to fish in wetlands.
- The impacts of habitat fragmentation are not as well documented for birds and mammals as they are for other taxonomic groups. There are different patterns of habitat use between groups of birds and mammals that can influence how they respond to fragmentation (Johnson and O'Neil 2001).

4.12 Impacts from Other Human Disturbances

There are many different human activities on the land which create disturbances that can impact wetland functions and values. The previous discussion addressed only impacts from disturbances caused by activities that have been extensively studied. The following sections review some of the impacts of other types of activities and disturbances that have been documented to a lesser extent. The discussions in these sections are not separated by wetland function because all of the impacts address either plants or wildlife, and the information is not extensive enough to warrant subdividing by functions.

4.12.1 Impacts on Plant Communities from Altering Soils

Physically disturbing wetland soils during the dry season, through tillage, compaction, excavation, or other means, can allow invasion by non-native plant species (Morin et al. 1989, Sutton 1996, David 1999, Galatowitsch et al. 1999). It can also destroy much of the viable seed bank (Lee 1991). Tilling the soil often reduces diversity, including both richness and evenness, as documented in a Carolina bay wetland (Kirkman and Sharitz 1994). The tillage treatment disrupted the roots of perennials more than burning, and it encouraged germination of annuals in the seed bank and colonization by several invasive species.

Invasive plants, especially non-native plants, significantly alter the species composition of many wetlands, sometimes even forming nearly monotypic stands. Among the most widespread invaders in North America are cattail (*Typha*), reed canarygrass (*Phalaris* sp.), purple loosestrife (*Lythrum salicaria*), giant reed (*Phragmites* sp.), milfoil (*Myriophyllum spicatum*), and hydrilla (*Hydrilla verticillata*). Their increased dominance is frequently attributed in part to the physical disturbance of soils or water levels within a wetland and/or the surrounding landscape, including accelerated sedimentation, eutrophication, and the construction of mitigation wetlands (Confer and Niering 1992, Magee et al. 1999).

Continuously disturbing the soil, for example through compaction and road building, can alter species composition. These disturbed conditions can lead to a decline in both the biomass of native species and a change in the soil conditions that support them (Ehrenfeld and Schneider 1991). Use of all-terrain vehicles also impacted wetlands on the Atlantic coastal plain, reducing the density of seed in wetland seed banks and allowing common rushes to displace rare species (Wisheu and Keddy 1991). Excavation and clearing of gas pipeline rights-of-way through forested wetlands in Florida resulted in increased species richness within the wetland clearings but an increased percent cover of non-native species (Van Dyke et al. 1993).

4.12.2 Impacts on Wildlife from Roads

Roads have been found to contribute to lower species richness for a variety of wildlife groups through the factors listed below. While most of the studies cited in this section were conducted in other regions of the country, much of the information is likely to pertain to effects on Pacific Northwest wildlife because the types of impacts described are inherent to

roads regardless of region, and many of the species impacted are also found in the Northwest. Furthermore, Findlay and Bourdages (2000) note that there may be long time lags between road construction and the time when effects on wildlife are perceptible. Impacts may be undetectable in some species for decades.

It is theorized that roads cause the loss of biodiversity by (Findlay and Bourdages 2000):

- Restricting movement between populations of wildlife
- Increasing mortality from road kills
- Fragmenting habitat
- Increasing edge habitat that increase the habitat for "generalist" species
- Facilitating invasion by exotic species
- Increasing human access to wildlife habitats

The following studies have documented the impacts of roads on different species of wildlife.

- In wetlands of southeast Ontario, the species richness of mammals, amphibians, reptiles, and birds was seen to decline with increased road density and forest removal (Findlay and Houlahan 1997).
- The numbers of frog and toads decreased with increasing traffic in a study by Fahrig et al. (1995). This study concluded that increased road density can contribute to a decline in the abundance of amphibians in urbanizing areas.
- A study of amphibians using small isolated wetlands in Florida found high mortality during migration between upland terrestrial habitats and temporary pond breeding habitats (Means 1996). The author attributes much of this to direct road mortality.
- A study of the "road-effect zone" of a four-lane suburban highway in Massachusetts was undertaken to determine the distance from a road that impacts can be measured (Forman 1998). This study concluded that the road blocks migration routes for salamanders up to several hundred meters from wetlands. The study also showed that the effect of the road on blocking major travel corridors between suitable habitat patches for small mammals could be measured to several kilometers from the road. The effects of traffic noise on birds could be measured up to 2,132 feet (650 m) from the road in forested areas and 3,051 feet (930 m) in open areas.
- A related study of the same Massachusetts highway showed that impacts on populations extended out at least 328 feet (100 m) from the highway. Forman and Deblinger (2000) studied nine ecological factors relating to, among other things, wetlands, streams, and amphibians. Assessing all factors, this study concluded that the "road-effect zone" averaged approximately 1,969 feet (600 m) wide, though it was quite variable in width at specific locations.
- In a study within the Columbia Basin, roads were found to increase human access and disturbance to fish and wildlife habitats, and this may reduce the number of waterfowl

using easily-accessed wetlands by an order of magnitude during the late-fall and winter months (Foster et al. 1984).

4.12.3 Impacts on Wildlife from Noise

The impacts of noise on wildlife are a topic of growing concern. The frequency of the sound waves and the duration of the sounds influence how noise affects wildlife species. Although many of the studies discussed below do not address wetlands specifically, the impacts of noise are not expected to change whether the species in question is in a wetland or another type of habitat.

Frequency is the pitch of a sound, and different animals show different sensitivities to the same range of frequencies. Generally, smaller mammals such as rodents, shrews, and bats have a greater sensitivity to higher frequencies—often within ranges exceeding 20,000 Hertz (Hz), the upper limit of human sound perception. Larger mammals show sensitivity to low frequencies and may be able to detect sound at or below 10 Hz. While most birds show a sensitivity to sound that is similar to humans (20 to 20,000 Hz), certain birds (such as rock doves) can also perceive low-frequency sounds, often with much greater sensitivity than their larger mammalian counterparts (Kreithen and Quine 1979). Some frogs and toads also show low-frequency sensitivity and even some small mammals are capable of discerning sounds of only a few Hertz (Plassman and Kadel 1991).

Sound duration may be divided into two classifications: continuous sounds which last for a long time with little or no interruption, and impulse sounds lasting for only short durations (Larkin et al. 1996). Impulse sound and continuous sound appear to have different physiological and behavioral effects. Generally, impulse noise appears to be more stressful to wildlife, at least in part due to the unpredictability of such noise (Larkin et al. 1996).

Overall, the literature suggests that species differ widely in their physiological response to various types, durations, and sources of noise (Manci et al. 1988). However, noise effects on wildlife may be broadly classified as primary, secondary, and tertiary:

- **Primary effects.** Are direct, physiological changes, such as stress and hypertension, to the auditory system and may be considered to include the "masking" of auditory signals. Masking is the inability of an individual to hear important environmental signals such as calls from mates or noises of predators or prey.

- **Secondary effects**. May include behavioral modifications that include interference with mating or reproduction and impaired ability to obtain adequate food, cover, or water.

- **Tertiary effects.** Are the direct result of primary and secondary effects at a population level and include population decline and habitat degradation. Most of the effects of noise are mild enough that they may never be detectable as variables of change in population size or population growth against the background of normal variation (Bowles 1995).

The behavioral responses of wildlife to noise show a high degree of variation depending on the species, the type of noise, and the habituation of the individuals to the source of noise. For example, some bald eagles can be very tolerant of auditory stimuli when the sources are screened from view (Stalmaster 1987), but other raptor species such as prairie falcons flush from perches and nests at sudden loud noises (Harmata et al. 1978).

Animals may become tolerant of repeated noises. Krausman et al. (1986) studied desert ungulates exposed to aircraft noise and noted that short-term habituation to aircraft noise occurred with repeated exposure. Sandhill cranes nesting meters away from a Florida highway showed no response to passing traffic (Dwyer and Tanner 1992). The effects of noise vary not only with the type of noise in question, but with an individual animal's experience, time of day (Herbold et al. 1992, Gese et al. 1989), and reproductive cycle (Platt 1977).

Research on the effects of traffic noise on breeding birds was conducted by Reijnen et al. (1995, 1996) who studied woodland and grassland bird populations in the vicinity of roadways. Ambient noise up to a given level resulted in no reduction in the density of bird populations. However, once an ambient noise threshold level was exceeded, densities decreased exponentially with increased noise. Threshold levels were found to range from 36 to 58 decibels, depending upon species, and the zones of decreased breeding densities surrounding the roadways ranged up to 2,670 feet (810 m) for particularly sensitive species near busy roadways. They found habitat avoidance by individual birds in habitat that would otherwise have been suitable for breeding.

One study also found evidence that reproductive output may be diminished in frogs breeding near highways because of acoustic interference (Barass 1985 in Larkin et al. 1996).

4.12.4 Impacts on Wildlife and Plant Communities from Recreational Activities

Little information was found on the impacts of recreational activities in wetlands. Most of the available information is anecdotal and focused on the more evident impacts such as loss of vegetation from the use of off-road vehicles. There is less information on the effects on wildlife of such disturbances as noise, light, glare, and human presence caused by recreational activities, particularly with respect to wetlands. None of the studies described in this section were located in the Pacific Northwest.

A synthesis paper on management of amphibians in Montana notes that among the many factors that are likely to contribute to a decline in amphibian populations are trail development, on- and off-road vehicles use, and development and management of recreational facilities (Maxell 2000). Citing a number of studies from the 1980s, Klein (1993) notes that recreational uses in natural areas can disrupt:

- Wildlife foraging and social behavior
- Animals that are feeding

- Parent-offspring bonds
- Pair bonds

The author also cites several studies stating that increased predation of nests and decreased densities of wildlife result from greater human recreational use of natural areas.

A study of flooded gravel pits in Britain examined the abundance and distribution of one species of wintering waterfowl with regard to recreational disturbance (Fox et al. 1994). The authors found that water-based recreational activity, such as boating, reduced the number of birds on the ponds to the greatest extent of all the observed activities. Ponds where fishing, walking, or other bank-side activities were allowed also showed reduced numbers of birds in comparison to the ponds that were designated reserves with restricted access. They were, however, not as reduced in abundance as those ponds that also allowed water-based activities.

The effects of recreational use on waterfowl were also studied in areas near the shore on Lake Erie (Knapton et al. 2000). Excessive human disturbance reduced the foraging efficiency and body fat acquisition for waterfowl and can result in decreased bird densities. Diving ducks appeared to be the most sensitive to disturbance.

In another study on recreation impacts on birds, Klein (1993) studied the specific behaviors of humans that disturb wildlife on a subtropical barrier island that is a National Wildlife Refuge off the coast of Florida. Her study sites were primarily in mudflat and mangrove wetland habitats. She tested a variety of treatments such as driving by without stopping, stopping the vehicle with and without getting out, approaching the birds on foot, and playing noise tapes. The author found that most of the bird species present were disturbed by the noise tape. Some species such as great blue heron consistently flew away when approached by a person, whereas other species tolerated human presence until closely approached.

Klein (1993) concludes that car traffic is less disruptive to wildlife than out-of-vehicle activity. Frequent human approaches may cause some bird species to forage in areas with fewer intrusions. Wildlife photographers were the most likely visitors to approach birds. Visitors who spoke with refuge staff and volunteers were the least likely to disturb birds, possibly due to an increased awareness of the habitat needs of wildlife. While this study involved a very different ecosystem, it is useful because it generated data on the Great Blue Heron, a bird species that also occurs in Washington. It also is one of the few studies that examined the effects of specific human behaviors on wildlife.

Recreational activity is believed to be one of the main factors in lakeshore deterioration and decline in reed-dominated wetlands in a study of Central European lakes (Ostendorp et al. 1995). It is likely that trampling of bank-side vegetation by recreational users is causing bank erosion and excessive siltation in wetlands near the shore.

Although recreation often occurs in more rural habitats, urbanization also brings increased intensity of recreational uses within remaining greenbelts and open spaces. A study in Western Australia examined the trend in smaller lot size relative to the owners' use of nearby open spaces (Syme et al. 2001). Smaller lot size resulted in an increase in recreational visits

by the homeowners to nearby wetlands. Increased access to and recreational use of wetlands is clearly one of the impacts that accompany urban development.

4.12.5 Introduction of Invasive and Exotic Species in Wetlands

Human activities increase the likelihood of introducing exotic animal and plant species to wetlands because they cause disturbances that favor the establishment of exotic species (Mack et al. 2000). The following factors have been found to favor the establishment of exotic species (Houck 1996, Dale et al. 2000, Mack et al. 2000, Gelbard and Belnap 2003, Maurer et al. 2003):

- Increased movement of seed and animals through higher road densities
- Greater fragmentation of the landscape that limit re-colonization of native species
- Higher densities of human land use
- Alterations of water regimes
- Direct disturbance of soils

The studies cited in the following discussion implicate disease, predation, and competition as major factors in limiting the success of native species when exotic, invasive species come in. Many of the relationships between invasive species and native species are not well understood because many environmental and biological factors play a role (Mack et al. 2000).

In Washington and Oregon, about 42 exotic vertebrate species have established populations (Witmer and Lewis 2001). These include species of 18 birds, 19 mammals, three reptiles, and two amphibians. The birds were mainly introduced for hunting or aesthetic purposes, while the mammals mostly escaped from commercial or domestic settings. The amphibians and reptiles were released pets or were introduced for food or aesthetic purposes. About 30% of these exotic species are restricted to freshwater and riparian systems, although others among this group will commonly use these habitats (Witmer and Lewis 2001). No information, however, was found on the number of exotic plant species found in wetlands.

4.12.5.1 Impacts on Wetlands from Exotic and Invasive Plants

Invasive plants, especially non-native invaders, significantly alter the composition of plant communities in many wetlands, sometimes even forming nearly monotypic stands (Adamus et al. 2001). Changes in the plant community can be expected to result in changes to all the invertebrates and microscopic organisms that are associated with specific plant species.

Among the most geographically widespread invaders in Washington's wetlands are reed canarygrass (*Phalaris arundinaceae*), purple loosestrife (*Lythrum salicaria*), giant reed (*Phragmites* sp.), and European milfoil (*Myriophyllum spicatum*). Their increased

dominance is frequently considered to be a result of human disturbances such as the following:

- Changes in soils or water levels within a wetland and/or the surrounding landscape, including accelerated sedimentation, eutrophication, and the construction of mitigation wetlands (Confer and Niering 1992, Magee et al. 1999)
- Changes in hydroperiod following urbanization (Cooke and Azous 2001)
- Increased human access and mechanical disturbance of wetlands (e.g., a study in southern Australia showed that vegetation removal and site disturbance are major factors in plant invasions; Detenbeck et al. 1999)
- Increases in sediment and nutrients resulting from agriculture or urbanization (Maurer et al. 2003).

4.12.5.2 Impacts on Species Using Wetlands from Domestic Pets

No information on the impacts of domestic pets on specific wetland-associated species was found. However, general information on predation by pets, specifically cats, indicate they can impact populations of many different small species living adjacent to residential areas. Residential development typically brings increased access to wetlands by domestic pets, primarily cats and dogs because wetlands are not fenced off.

Several studies of predation by house cats indicate that small mammals and birds were the preferred prey of house cats, but cats also killed reptiles and amphibians (Barratt 1997, Lepczyk et al. 2003). Many of the mice and rats captured by the cats are exotic species themselves. The results, however, suggest that house cats may have significant impacts on native populations as well, particularly along the fringes of suburban expansion where native mammals and birds are more common.

A study of predation by house cats in Virginia determined that individual cats caught an average of 26 animals in urban areas and 83 animals in rural areas over an 11-month period (Mitchell and Beck 1992). In another study in Michigan, Lepczyk et al. (2003) found that cats preyed on about 1 bird per week. Extrapolating these numbers of prey to the total number of cats in a specific urban or suburban area would give an astonishingly high toll attributable to house cats.

4.12.5.3 Impacts on Species Using Wetlands from Exotic Mammals and Birds

Many introduced birds are known to usurp nests of native birds or to compete with them for nest sites. European starlings (*Sturnus vulgaris*) are known to displace wood ducks, woodpeckers, and other species from their nests, often destroying the eggs and young (Witmer and Lewis 2001). Starlings also out-compete many native species for nest cavities, overwhelming them with their large numbers and aggressive behavior. Transmission of

disease, particularly from exotic birds and rodents from Europe, is also a major problem that threatens native wildlife (Witmer and Lewis 2001).

Introduced mammals affect native wildlife and plants through predation and herbivory (Witmer and Lewis 2001). For example, nutria (*Myocaster coypus*), which were introduced from South America for fur production, have tremendous impacts on wetland vegetation, uprooting plants as they dig for rhizomes and denuding vast areas (Mitsch and Gosselink 2000, Witmer and Lewis 2001). Nutria may be implicated in population declines of muskrats (*Ondatra zibethicus*), probably due to competitive exclusion (Witmer and Lewis 2001).

4.12.5.4 Impacts on Native Invertebrates from Exotic Invertebrates in Wetlands

Humans have introduced a number of non-native invertebrates to wetlands. Native invertebrate communities seem ill-adapted to compete with or avoid these alien species, but data on long-term effects to wetland communities are mostly lacking.

The zebra mussel (*Dreissena polymorpha*) has invaded many aquatic systems throughout North America. Although the zebra mussel has not yet been found in Washington, some local populations of mussels that live in wetlands may be highly susceptible if an invasion occurs. Some mussels (of the family Unionidae which is found in Washington streams and rivers) are particularly susceptible to disruptions from introduced mussels because they are relatively immobile and have long life spans, often over 10 years (Mehlhop and Vaughn 1994). Furthermore, riverine wetlands with higher alkalinity tend to be more susceptible to invasions by zebra mussels (Whittier et al. 1995).

In areas in other parts of the country that have been invaded by Zebra mussels substrates can become totally carpeted, displacing native mussels (Tucker and Atwood 1995). Some midges, snails, and caddisflies can be outcompeted as well. The mussel has minimal or positive effects on amphipods and flatworms (Wisenden and Bailey 1995). They may also concentrate contaminants, making them more available to invertebrate food chains (Bruner et al. 1994).

The rapid spread of zebra mussels may have been made more possible by the preceding decline of native mussels as a result of pollution and changes in habitat (Roberts 1990, Nalepa and Schloesser 1993, Mackie 1991, Haag et al. 1993, Whittier et al. 1995).

4.12.5.5 Impacts on Native Amphibians from Exotic Species in Wetlands

The effects of exotic species of amphibians on native amphibians that use wetlands are particularly well studied, but not well understood. Predation and competition from introduced amphibians has been suggested as one cause of population declines for native amphibian species (Witmer and Lewis 2001), but as described below the effects are complex.

Bullfrogs (*Rana catesbeiana*) are often cited as a factor in declining amphibian populations (Hecnar and M'Closkey 1996, Kiesecker and Blaustein 1998, Adams 1999a). Native to

eastern North America, bullfrogs were introduced to the Pacific Northwest in the early 1900s for hunting and food. Bullfrogs are suspected of causing amphibian declines because they prey on frogs and salamanders and are often so numerous in wetlands that they are thought to out-compete native species for space (Witmer and Lewis 2001). Studies of the role that bullfrogs play in declines of amphibian populations are, however, somewhat contradictory in their findings (Hecnar and M'Closkey 1996, Kiesecker and Blaustein 1998, Adams 1999a, Witmer and Lewis 2001). It is possible that the effects of bullfrogs may differ for various species, or their influence may be quite subtle and complex.

Several studies conducted in the Pacific Northwest have found either weak or no correlation between bullfrog presence and amphibian richness and abundance (Adams 1999a, Richter and Ostergaard 1999, Richter and Azous 1995). Data from a monitoring program of amphibians in wetlands in King County showed that bullfrogs are not causing competitive exclusion of native species (Richter and Ostergaard 1999). Native amphibian richness was not negatively correlated with bullfrog presence or with the presence of permanent water in the wetlands (Richter and Ostergaard 1999). Richter and Azous (1995) noted relatively high species richness for native amphibians in permanently ponded wetlands, the preferred habitat for bullfrogs.

Focusing on red-legged frogs (*Rana aurora*) in Puget Lowland wetlands, Adams (1999a) concluded that this species is not excluded from wetlands that also support bullfrogs. The study showed little to no negative correlation between red-legged frogs and bullfrogs. It noted that exotic fishes such as sunfish, yellow perch (*Perca flavescens*), and smallmouth bass (*Micropterus dolomieui*) had greater effect on amphibian richness in the wetlands studied. In a companion study Adams (1999b) found that habitat gradients or indirect effects of exotic vertebrates on native amphibians play major roles.

A study of red-legged frogs in the Willamette Valley in Oregon, however, stated their development was affected by both bullfrogs and exotic fishes (Kiesecker and Blaustein 1998). In this study, tadpoles showed decreased mass at metamorphosis and increased time to metamorphosis in the presence of larval and adult bullfrogs. Smallmouth bass alone had little effect on tadpole development, but red-legged frog tadpoles altered their use of microhabitats when both bullfrogs and smallmouth bass were present. Survival of tadpoles was affected only when both bullfrog adults and larvae were present, or when both bullfrog larvae and smallmouth bass were present.

4.12.5.6 Impacts on Wetland-associated Species from Exotic Fish

Non-native fish have been widely introduced into waters of the United States and Washington, both intentionally and by accident. Adamus et al. (2001) cite research showing that the effects of invading species on native fish communities are usually adverse (Baltz and Moyle 1993), especially when coupled with simultaneous impacts from other factors (Larimore and Bayley 1996, Marschall and Crowder 1996).

The presence of exotic fish has been implicated in reduced abundances and species richness of amphibians. A study in the Okanogan Highlands in northeast Washington showed that richness of pond-breeding amphibian and abundance were diminished by the presence of

exotic fish (Aker 1998). The non-native fish species observed in this study included largemouth bass, tench (*Tinca tinca*), brook trout (*Salvelinus fontinalis*), and perch. While there was lower amphibian richness in ponds with native fish than those with no fish, the data indicate that non-native fish had a greater impact on amphibian numbers and richness. Adams (1999a, 1999b) found that exotic, non-native, fish reduced survival of native amphibians to almost zero in the Puget Lowlands. Further studies by Adams (Adams et al. 2003) found that non-native fish facilitated the invasion of wetlands in Oregon by bullfrogs because they fed on invertebrate predators of bullfrog larvae.

Leonard et al. (1993) surveyed populations of the northern leopard frog (*Rana pipiens*) in Washington State. They found that the species had been extirpated from most of its historic range, with only small populations remaining in parts of eastern Washington. These authors noted that areas once inhabited by the northern leopard frog support exotic species such as largemouth bass (*Micropterus salmoides*), black crappie (*Pomoxis nigromaculatus*), yellow perch (*Perca flavescens*), and brown bullhead (*Ameiurus nebulosus*). They hypothesized that these species may be implicated in the decline of the northern leopard frog but have no definitive data to support this hypothesis.

The introduction of carp has resulted in significant impacts on wetlands in eastern Washington. Large, herbivorous fish such as carp compete directly with birds for submerged aquatic plants (Bouffard and Hanson 1997). The fish also resuspend the sediments on the bottom of lakes and ponds. This has a significant impact on invertebrates as well as the submerged aquatic plants. Parkos et al. (2003) found that the presence of the common carp was positively correlated with increases of phosphorus (a nutrient that causes eutrophication), turbidity, suspended solids, and zooplankton biomass. Their presence was negatively correlated with the abundance of aquatic plants and invertebrates.

4.12.6 Summary of Key Points

- Alteration of soils can change the plant community in a wetland and allow invasion by exotic species.
- Noise creates stress for wildlife, but the impacts are very specific to individual species and to the type of noise generated.
- Recreational use of wetlands impacts the normal behavior of wildlife and reduces densities.
- Invasions by exotic species can alter the distributions of both plant and animal species in wetlands. The impacts of bullfrogs on other amphibians, however, seem to be ambiguous even though this question has been studied extensively.

4.13 Chapter Summary and Conclusions

Humans create many different types of disturbances that can affect the performance of wetland functions. The disturbances were reviewed in Chapter 3. Chapter 4 has reviewed the information available on how each type of human disturbance impacts wetlands and their functions. The disturbances that impact wetlands the most include:

- Direct changes to the physical structure of wetlands via filling, vegetation removal, tilling of soils, and compaction of soils
- Changes in the amount of water in wetlands
- Changes in how water levels fluctuate (frequency, amplitude, direction of flows)
- Changes in the amount of sediment
- Increases in the amount of nutrients
- Increases in the amount of toxic contaminants
- Changes in the amount of acidity
- Increasing the concentration of salts
- Increasing the fragmentation of habitat
- Other disturbances that are not as well documented including alteration of soils, construction of roads, noise, recreational use, and invasion by exotic species.

Table 4-3 reviews how various land-use practices create disturbances that can change the environmental factors that control wetland functions. Table 4-4 summarizes the effects of each of these disturbances in terms of the wetland functions they may impact. The rating of the impacts in the table represents a synthesis by the authors of all the information presented in this chapter. By combining the information in these two tables, it is possible to associate changes in functions of wetlands with general types of human land use, as shown in Table 4-5. The human land uses create various disturbances in the environment, and those disturbances in turn affect the factors that control wetland functions, ultimately leading to changes in those functions.

For example, Table 4-3 shows that urbanization creates significant disturbances that change the amount of water, the fluctuations of water levels, and input of sediments, nutrients, and contaminants to wetlands. Table 4-4 shows that these disturbances have a major impact on the wetland functions of providing habitat for plants, invertebrates and reptiles/amphibians. Table 4-5 synthesizes this information to show that urbanization impacts the habitat for plants, invertebrates, reptiles, and amphibians in wetlands.

The scientific information available indicates that human activities and uses of the land can have significant impacts on the functions in wetlands at both the larger, landscape scale and at the scale of the individual wetland itself. As a result many different approaches have been

developed to try to minimize these impacts. These include regulations to control human activities near wetlands, methods to replace the functions lost or altered including restoration, ways to protect the wetland resource through non-regulatory measures and incentives. The effectiveness of some of these tools at actually protecting wetland functions are discussed in Chapters 5 and 6.

Table 4-3. Summary of types of environmental disturbances created by some types of land use.

Disturbance	Scale of Disturbance	Agriculture	Urbanization	Mining
Changing the physical structure within wetlands (filling, vegetation removal, tilling of soils, compaction of soils)	Site scale	xx	xx	h
Changing the amounts of water	Landscape scale	xx	xx	?
	Site scale	xx	xx	h
Changing fluctuations of water levels (frequency, amplitude, direction of flows)	Landscape scale	xx	xx	?
	Site scale	xx	xx	h
Changing the amounts of sediment	Landscape scale	xx	xx	h
	Site scale	xx	xx	h
Increasing the amount of nutrients	Landscape scale	xx	xx	nm
	Site scale	xx	xx	nm
Increasing the amount of toxic contaminants	Landscape scale	xx	xx	x
	Site scale	xx	xx	xx
Changing the acidity	Landscape scale	nm	nm	x
	Site scale	nm	nm	xx
Increasing the concentrations of salt	Landscape scale	x	nm	nm
	Site scale	x	nm	nm
Fragmentation	Landscape scale	xx	xx	h
Other disturbances	Site scale	xx	xx	h

Key to symbols used in table:

(xx) Land use creates a major disturbance of environmental factors

(x) Land use creates a disturbance

(nm) Studies on impacts of this land use do not mention this disturbance

(h) Literature is lacking but disturbances can be hypothesized based on authors' experience

(?) Information lacking

Table 4-4. Synthesis of the information reported in the literature on the negative impacts of different human disturbances on wetland functions.

Disturbance Type	Functions							
	Hydrologic	Water Quality	Plants	Habitat for Invertebrates	Habitat for Amphibians and Reptiles	Habitat for Fish	Habitat for Birds	Habitat for Mammals
Changing the physical structure of wetlands	+	+	++	++	+	+	++	+
Changing the amount of water	+	+	++	++	++	+	+	?
Changing fluctuations of water levels	?	?	++	+	++	+	?	?

Chapter 5

The Science and Effectiveness of Wetland Management Tools

5.1 Reader's Guide to this Chapter

This chapter builds on the previous discussion of how wetlands function (Chapter 2), how human activities and changes in land use cause disturbances (across the landscape and at specific sites) that influence the factors that control wetland functions (Chapter 3), and how wetland functions are impacted by these disturbances (Chapter 4).

Chapter 5 presents a synthesis of what the current literature reports on four tools currently used to identify wetlands and to address impacts to wetlands and their functions: wetland definitions, wetland delineation methods, wetland ratings, and buffers. This chapter does not provide language or recommendations for regulatory or policy language—those will be provided in a separate volume on management options and recommendations (Volume 2).

5.1.1 Chapter Contents

Major sections of this chapter and the topics they cover include:

Section 5.2, Introduction and Background on Regulatory Tools introduces the key wetland management tools that are discussed in this chapter.

Section 5.3, How Wetlands Are Defined and Delineated describes similarities and differences in the way various agencies define *wetland*. It explains the critical difference between "biological wetlands" and "regulated wetlands." It also discusses certain types of wetlands that are frequently exempted from regulation, such as isolated wetlands, small wetlands, or those designated as Prior Converted Croplands. The various manuals that have been developed to guide the delineation of wetland boundaries are also briefly discussed.

Section 5.4, Wetland Rating Systems discusses how rating systems have been developed to rapidly assess wetland characteristics in the field. These characterizations allow wetlands to be rated for regulatory or management purposes. This section introduces the reader to the Washington State wetland rating systems, which were briefly mentioned previously in a number of places in the document. It also includes discussion of certain wetland types that require particular attention under the Washington State wetland rating systems.

Section 5.5, Buffers comprises the bulk of this chapter. This section provides a synthesis of the literature on how buffers protect and maintain wetland functions. The section concludes by summarizing recommendations from the literature for establishing effective buffer widths.

Section 5.6, Chapter Summary and Conclusions ties together the major concepts presented in the chapter.

5.1.2 Where to Find Summary Information and Conclusions

Each major section of this chapter concludes with a brief summary of the major points resulting from the literature review on that topic in a bulleted list. The reader is encouraged to remember that a review of the entire section preceding the summary is necessary for an in-depth understanding of the topic.

For summaries of the information presented in this chapter, see the following sections:

- Section 5.3.6
- Section 5.4.2
- Section 5.5.3.5
- Section 5.5.4.4
- Section 5.5.5.4
- Section 5.5.6.1

In addition, Section 5.6 provides a summary and conclusions about the overarching themes gleaned from the literature and presented in this chapter.

5.1.3 Data Sources and Data Gaps

No literature review was conducted for the section on wetland definitions or delineations. Both of these management tools are currently established by state and federal statutes. It was determined that review of the previous discourse on these topics was not relevant to the current state of the science for Washington State.

Considerable research was published prior to 2000 on the role of small wetlands relative to wildlife in a landscape context. Since then, several synthesis documents on small and isolated wetlands have been published.

Papers on the adequacy or effectiveness of wetland rating systems were not found; instead, the literature concentrates on function assessment methods. This chapter does not attempt to assess the science on wetland function assessment because the Washington State Department of Ecology (Ecology) has evaluated and described different function assessment methods previously (see Volume 2, Appendix 5-B for more information). Additionally, Ecology completed function assessment methods for several different

wetland hydrogeomorphic types on both sides of the state within the last five years (see Chapter 2 for further information).

The subject of buffers is well documented in the scientific literature. Numerous studies from across the U.S. have been conducted for wetland and stream buffers. The results of buffer studies, completed here in the Pacific Northwest as well as other areas of the country, provide remarkably consistent findings related to the factors that are important in determining appropriate buffer widths. This consistency is particularly striking in the numerous buffer synthesis documents. Additionally, the results of many studies conducted in other parts of the U.S. have been replicated in studies in the Pacific Northwest.

Determining relevance to Washington, however, can be challenging, since the physical settings of the studies vary widely. Some, however, obviously do relate to Washington; for example, literature related to agricultural practices and vegetated filter strips from the north-central United States and south-central Canada is relevant to some agricultural practices in Washington, especially in areas east of the Cascades.

The majority of research on buffers tends to focus on how buffers influence water quality. Far fewer studies examine the influence of a buffer's physical characteristics on attenuating rates of surface water flow.

Most studies on buffers related to wildlife document the needs of a particular species or guild related to how far they travel from aquatic habitats to fulfill their life-needs. While there is substantial literature on the implications of habitat fragmentation, this literature does not specifically address the role of buffers in reducing fragmentation between wetlands and other parts of the landscape.

Numerous compilations and syntheses of the literature concerning buffers have been completed since 1990. These synthesis documents are used in this document as direct sources when no more recent research was found. This chapter also cites literature related to stream buffers and riparian areas when the findings are relevant to the functions or processes these areas provide to the adjacent aquatic resource.

A more detailed description of the types of literature used and any recognized gaps in the scientific literature are provided within each section on buffers as appropriate.

5.2 Introduction and Background on Regulatory Tools

The regulatory tools discussed in this chapter are components of "typical" wetland protection programs. The intent is not to analyze all elements of protection programs and their regulations but to focus on the key science-based elements relating directly to wetland protection and management. Therefore, this chapter focuses on the following four elements:

- Wetland definitions
- Wetland delineation methods
- Wetland ratings
- Buffers

The topic of compensatory mitigation, another key regulatory tool, is discussed separately in Chapter 6 because of the volume of information and literature available on this subject.

5.3 How Wetlands are Defined and Delineated

5.3.1 How Agencies Define Wetlands

Several definitions of wetlands have been developed and used by various federal, state, and local agencies and jurisdictions. The effectiveness of current federal or state wetland definitions was not evaluated as part of this synthesis. However, definitions are included here because how a wetland is defined is critical to determining what areas are subject to the provisions of a law or regulation.

For the purposes of most laws and regulations, wetlands are usually defined using one of the following two definitions:

> *Those areas that are saturated or inundated by surface or groundwater at a frequency and duration sufficient to support, and under normal circumstances do support, a prevalence of vegetation typically adapted for life in saturated soil conditions. Wetlands generally include swamps, marshes, bogs, and similar areas.* (U.S. Army Corps of Engineers 1987);
>
> or
>
> *"Wetlands" or "wetland areas" means areas that are inundated or saturated by surface or ground water at a frequency and duration sufficient to support, and that under normal circumstances do support, a prevalence of vegetation typically adapted for life in saturated soil conditions. Wetlands generally include swamps, marshes, bogs and similar areas. Wetlands do not include those artificial wetlands intentionally created from non-wetland sites, including, but not limited to, irrigation and drainage ditches, grass-lined swales, canals, detention facilities, wastewater treatment facilities, farm ponds, and landscape amenities, or those wetlands created after July 1, 1990, that were unintentionally created as a result of the construction of a road, street, or highway. Wetlands may include those artificial wetlands intentionally created from nonwetland areas to mitigate the conversion of wetlands.* (Washington Administrative Code 173-22-030.)

The Washington State definition is derived from the U.S. Army Corps of Engineers (Corps) definition, but it also includes clarifying language that identifies which common human-made or -induced features are not meant to be defined as wetland. The state definition is required by the Growth Management Act (RCW 36.70A.030 (20)) to be used in all local critical area regulations.

In addition, for the National Wetland Inventory, the U.S. Fish and Wildlife Service (USFWS) defined wetlands as follows:

> *Wetlands are lands transitional between terrestrial and aquatic systems where the water table is usually at or near the surface or the land is covered by shallow water. For the purpose of this classification wetlands must have one or more of the following three attributes: (1) at least periodically, the land supports predominantly hydrophytes, (2) the substrate is predominantly undrained hydric soil, and (3) the substrate is nonsoil and is saturated with water or covered by shallow water at some time during the growing season of each year.* (Cowardin et al. 1979)

Note that the definition used by the USFWS allows the use of a single parameter to determine if an area is a wetland. The definition also includes areas that may not be vegetated, such as gravel bars and mudflats. In most cases, the Corps and Ecology definitions require the presence of all three parameters (vegetation, soil, and hydrology) for an area to be considered a wetland, and they both assume that wetlands generally are vegetated.

5.3.2 Biological vs. Regulated Wetlands

In some jurisdictions, all lands that meet the definition of *wetland* are regulated. However, it is not unusual for a jurisdiction to differentiate within its regulations between "wetlands" (i.e., biological wetlands) and "regulated wetlands" (i.e., wetlands that they intend to regulate). The definition of what constitutes a regulated wetland may vary from jurisdiction to jurisdiction.

In reviewing regulatory language from local wetland regulations, the three primary criteria used to differentiate between "wetland" and "regulated wetland" were:

- The category or rating of the wetland
- The size of the wetland
- The type of wetland (such as isolated wetlands and those designated as Prior Converted Croplands)

In general, a category or rating system has been used historically in regulatory language to differentiate between wetlands that need different degrees of protection. Rating systems are used by local jurisdictions to group wetlands based on physical characteristics and/or functions that the wetlands may provide and how those characteristics or functions are valued. Section 5.4 of this document describes the current

state of the science on wetland ratings and the wetland rating systems developed for eastern and western Washington.

The criterion of wetland size is usually a minimum below which the jurisdiction will not regulate a wetland. For example, the jurisdiction may allow no fill in wetlands larger than 10,000 square feet, or they may include language such as "Category 2 wetlands larger than 0.25 acre cannot be altered." The historical rationale for the use of size as a regulatory criterion was the perception that "bigger is better," and the belief that small wetlands were less important and did not provide significant functions. The scientific literature of the last 10 years has made it clear that size does matter but not in the way previously believed. In multiple studies, small wetlands have been shown to contain a significant diversity of plant and animal species (See Section 5.3.3 for more information).

Additionally, two other wetland types may be exempted from regulation: isolated wetlands and wetlands designated as Prior Converted Croplands.

In 2001, the U.S. Supreme Court determined that isolated wetlands are not subject to regulation under Section 404 of the federal Clean Water Act if the only basis for their regulation is their use by migratory birds. However, the Court did not define "isolated," and the federal government has not issued any new guidance or regulations to clarify the situation. In general practice, the U.S. Army Corps of Engineers (Corps), the federal agency that administers the Clean Water Act, considers isolated wetlands to be those of any size that are not adjacent to or have no direct surface water connection to any navigable waters. However, recent lower court decisions have interpreted Corps jurisdiction over isolated waters differently, and the situation is in flux.

Washington State has determined that isolated wetlands are regulated by the Department of Ecology under the state Water Pollution Control Act (RCW 90.48). Since some local jurisdictions in Washington fashion their wetland regulations on the federal or state standards, it is important to consider the implications of not regulating isolated wetlands. Thus, scientific information on isolated wetlands is discussed in Section 5.3.4.

Wetlands that are designated as Prior Converted Croplands (PCC) are another type of wetland that are exempt from regulation by the federal government. PCC are those wetlands that were drained or otherwise manipulated prior to December 23, 1985, for the production of commodity crops. They are wetlands in which inundation (ponding) does not occur for more than 14 consecutive days during the growing season. These sites must produce an agricultural commodity that requires planting a crop that needs annual tilling. These areas are considered waters of the U.S. if they are abandoned (i.e., tilling and planting has not occurred for five consecutive years), and hydrophytic vegetation and wetland hydrology returns. However, even if they are not abandoned, many of the PCCs in Washington still meet the three criteria required for biological wetlands. As with isolated wetlands, the Department of Ecology regulates PCCs that are wetlands under state law.

No information on wetland areas meeting the definition of PCC was found in the scientific literature. However, many wetlands meeting the criteria for PCC would still be expected to provide important functions, given that the criteria for being designated "Prior Converted" require only that the wetland has been manipulated for production of commodity crops since 1985 and does not pond for more than 14 consecutive days during the growing season. The authors of Volume I have observed widespread flooding in PCC areas during the winter and have observed use of these areas by several species of overwintering waterfowl. One published study of waterfowl in Puget Sound documented significant use of farmlands by several duck species for feeding during the winter (Lovvorn and Baldwin 1996). This study found greater use by waterfowl of farm fields that were flooded in winter, but made no distinction between upland farm fields, farmed wetlands, and Prior Converted Croplands. In addition, the authors of Volume I have documented significant water quality and quantity functions provided by PCCs in projects reviewed and permitted by the Department of Ecology (This data has not been published).

If the agricultural activities were abandoned, PCCs could revert to a plant community characteristic of wetland; and, without maintenance of the hydrologic modifications, the wetland's water regime may revert to a condition more like that which existed prior to the alteration. Further analysis of the functions of wetland areas designated as PCC is needed.

No literature was found that discussed the ecological consequences of the legal bifurcation between biological wetlands and regulated wetlands. However, literature was found that discusses the functions and values provided by small wetlands and isolated wetlands, as discussed below.

5.3.3 Small Wetlands

The elimination of small wetlands is an issue that has gained attention over the past 10 years. Many regulations have preferentially allowed filling of small wetlands. Many regulations completely exempt wetlands under a certain threshold. Also, size is one of the most common characteristics used in determining wetland ratings at the local level, and smaller wetlands typically receive lower levels of protection. Yet, the loss of small wetlands is one of the most common cumulative impacts on wetlands and wildlife (Weller 1988, Tiner et al. 2002).

No definition of *small* is provided here because what constitutes "small" varies between jurisdictions and scientific studies (see also Section 5.3.2). In some contexts, small is determined exclusively by size. Small may mean less than 0.10 acre; in others, it may mean less than 10 acres.

Some jurisdictions, however, also differentiate small wetlands using criteria that reflect function and values. Small wetlands can have outlets, be in a floodplain, or be otherwise associated with a larger aquatic system. These characteristics are often used in rating systems and, combined with size, determine what is considered a small wetland. For

example, a jurisdiction may include language in their regulations such as "Category 2 wetlands larger than 0.25 acre cannot be altered." For each of the studies below, we have included the authors' definition of small.

In addition to the obvious loss of habitat for wildlife, fragmentation of habitat increases as small wetlands are eliminated, resulting in greater distances between wetland patches in the landscape. Semlitsch and Bodie (1998) found that creating greater distances between wetlands of 0.5 to 10 acres in size can have a significant effect on the ability of a landscape to support viable populations of amphibians, as juveniles dispersing from a source wetland may not be able to travel far enough to recolonize other surrounding (now distant) wetlands. Management priorities have focused on larger, semi-permanent wetlands, with the least emphasis on protecting the smaller, seasonal wetlands (< 1.2 acres) that are critical components of wetland complexes (Naugle et al. 2001).

The following sections describe studies of the use of small wetlands by wildlife, and the role that small wetlands play in maintaining connections between habitats. For each of these studies, the authors' definition of small is described.

Studies of the relationship between wetland size and wildlife distribution have mostly focused on amphibians and birds. Few studies have examined how use of wetlands by mammals relates to wetland size, and no studies of this relationship were found for macroinvertebrates or reptiles. No studies were found that documented the role that small wetlands play in providing water quality or hydrologic functions. However, the degree to which small wetlands perform water quality or hydrologic functions is likely to be determined by site-specific characteristics (see Chapter 2) and can be estimated on a per-acre basis using some of the available function assessment methods.

5.3.3.1 Amphibians and Small Wetlands

Snodgrass et al. (2000) undertook a study of amphibian use of wetlands to address three commonly held beliefs about small wetlands (0.7 acres - 3 acres):

- They have short hydroperiods
- They support few species
- They support species that are also found in larger wetlands

Snodgrass et al. (2000) determined that amphibian species richness increases with length of hydroperiod. They also concluded that short-hydroperiod wetlands (smaller temporarily ponded wetlands) are also important in maintaining biological diversity in that they support species not found in larger wetlands with longer hydroperiods. The species they found in small wetlands were not a subset of those in larger wetlands but rather a unique group of species.

Similarly, amphibian richness in Puget Sound wetlands was found to have no correlation with wetland size (1 - 30 acres). High richness occurred in some of the smallest wetlands (Richter and Azous 1995). The study indicates that small wetlands that are vegetatively

simple can serve adequately as breeding habitats as long as favorable nonbreeding habitat is present nearby. Species richness also was not related to persistence of ponding.

Gibbs (1993) conducted a simulation model in Maine from which he theorized that small wetlands may be most important for wetland organisms with low population growth rates and low densities. The model demonstrated that the loss of small freshwater wetlands (less than approximately 5 acres [2 ha]) would result in a decline of total wetland area by 19% and total wetland number by 62%, while the average distance between wetlands would increase by 67% (Gibbs 1993). The model showed that the loss of small wetlands would result in a change (from 90% to 54%) of the area that would lie within the maximum migration distance of terrestrial-dwelling and aquatic-breeding amphibians. The risk of extinction would significantly increase for local populations of turtles, small birds, and small mammals that are currently stable even though the model showed no change in the risk of metapopulation extinction for salamanders or frogs. Amphibian populations in the study were buffered from the risk of extinction due to high rates of population increase. The model demonstrated that dispersal ability for amphibians is a predictor of population growth rate and density, not sensitivity of a population to loss of small wetlands.

5.3.3.2 Birds and Small Wetlands

Bird use of wetlands appears to have a stronger relationship to wetland size than that of amphibians. Bird richness was positively correlated with larger wetland size in a Puget Sound study of palustrine wetlands (Richter and Azous 2001b). This is attributed to the fact that larger wetlands in the study generally had greater structural complexity and a greater number of habitat types.

Martin-Yanny (1992) also found that bird species richness and abundance in wetlands of the Pacific Northwest are positively correlated with wetland size. However, Martin-Yanny noted that habitat heterogeneity was a more important determining factor than wetland area in influencing bird species richness. Wetlands in highly urbanized watersheds had fewer neotropical migrant species, fewer ground-nesting birds, and more edge-tolerant (habitat generalist) species. This is because urbanizing watersheds tend to have smaller wetlands (less than 10 acres [4 ha]) with more edge habitat, making birds more susceptible to competition, predation, and nest parasitism. The author recommends preserving large wetlands or complexes of smaller wetlands that are connected by extensive upland buffers.

In northern prairie marshes, bird species richness was also seen to increase with marsh size and to decrease as the wetland became more isolated (Brown and Dinsmore 1986). Marshes that were part of wetland complexes showed higher species richness than isolated wetlands. Certain bird species used smaller marshes only when the marshes were part of a wetland complex. Large isolated marshes in the study often had lower species richness than smaller marshes that were part of wetland complexes. While bird species richness increased, the rate of increase slowed as the marshes became larger. In other words, they concluded that prairie marshes in the size range of 49 to 74 acres (20 to 30 ha) were more efficient in preserving bird species than larger marshes.

A study of agriculturally disturbed wetlands in western Oregon reached similar conclusions in finding that larger wetlands support more bird species (Budeau and Snow 1992). These authors also showed that wetlands of all sizes were important to water-birds.

However, in eastern Washington, Foster et al. (1984) found that waterfowl breeding use of wetlands in the Columbia Basin was greatest in smaller wetlands (less than 1 acre [0.4 ha]).

5.3.3.3 Mammals and Small Wetlands

The study that modeled the effects of the loss of small wetlands in Maine showed that local populations of small mammals faced a significant risk of extinction following the loss of small wetlands (<5 acres) (Gibbs 1993). However, in a study of Puget Sound wetlands, Richter and Azous (2001c) concluded that wetland size alone was not a significant factor in determining mammal richness or abundance. They noted that small-mammal richness was most closely affected by the combined factors of:

- Wetland size
- Extent of retention of forest adjacent to the wetland
- Quantity of large woody debris within wetland buffers

In conclusion, the literature suggests that size is not a significant factor in contributing to most wetland habitat functions. Rather, habitat structure, connectivity, and wetland hydroperiod are much more significant factors in determining habitat functions than size alone. The literature emphasizes that small wetlands are critically important to amphibians, particularly when connectivity between wetlands and with adjacent uplands is maintained. However, none of the studies evaluated the role of wetlands less than 0.5 acre, so the implications of exempting wetlands less than 0.25 acre, as is commonly done in local wetland regulations, are unknown.

The next section deals specifically with isolated wetlands. The following excerpt from Moler and Franz (1987) describes small, isolated wetlands and sheds some light on the attributes of both size and isolation.

> *To a great extent, the unique values and functions of small, isolated wetlands have been overlooked. This oversight derives from several factors, perhaps foremost being the general tendency to think of small wetlands as being little more than subsets of larger wetlands. So long as the uniqueness of small wetlands is unrecognized, then it is intuitive to think of wetlands as declining in value directly as function of size. Similarly, so long as the unique values of isolated wetlands are unrecognized, it is understandable that connected wetlands might be considered of greater value. In reality, small isolated wetlands are biologically unique systems. Because of their isolation and small size, they support a very different assemblage of species than that found in*

larger, more permanently wet situations. The ephemeral nature of many small wetlands makes them unsuitable for species which require permanent water.

5.3.4 Isolated Wetlands

Isolated wetlands are being addressed in this document because of the recent Supreme Court decision to exclude many isolated wetlands from federal regulation. The Supreme Court decision regarding isolated wetlands was made based on a legal interpretation of jurisdiction under the federal Clean Water Act (Solid Waste of Northern Cook County v. United States Army Corps of Engineers). The key factor was the language in the Act that relates to navigable waters. The Court did not rule that isolated wetlands are less important than non-isolated wetlands, only that the intent of Congress in passing the Clean Water Act was to relate the protection of waters of the United States to navigability. The Court also did not provide any definition of what constitutes "isolation" for purposes of jurisdiction.

The Seattle District of the U.S. Army Corps of Engineers (Corps) does not have any national or regional guidance for making isolated wetland determinations. As of November 2004, if a wetland meets the test of "adjacency" (neighboring, bordering or contiguous) with any navigable water, or if the wetland has a surface outlet that drains to a navigable water, then the Corps does not consider it isolated (T.J. Stetz, U.S. Army Corps of Engineers, Seattle, personal communication 2004). Future court or administrative decisions may change how isolated wetlands are determined.

Much confusion has resulted from this decision, and some in the public have assumed that isolated wetlands are less important or less worthy of protection. Therefore, it is important to summarize some of the basic science on isolated wetlands, which is presented in the paragraphs that follow.

Much of the information comes from the work of Tiner et al. (2002) and a recent issue of *Wetlands* (Volume 23, #3, 2003) that includes numerous articles on isolated wetlands. Readers are directed to this work for more detailed information. Additionally, the work of Hruby et al. (1999, 2000) in developing assessment methods for wetland functions in Washington provides important scientific information on depressional wetlands in Washington, a wetland type that contains the majority of isolated wetlands in Washington.

Wetlands can be defined as isolated based on their geographic isolation, ecological isolation, or hydrologic isolation (Tiner et al. 2002). For this discussion, isolated wetlands are defined by a very specific type of hydrologic isolation—they do not have a surface outlet by which water leaves the wetland, even seasonally, to another water body. Although frequently described as closed depressions (Tiner et al. 2002, Winter and LaBaugh 2003), isolated wetlands can also be sloped wetlands where surface water, if present, re-enters the shallow groundwater zone at the base of the wetland and is not linked via surface flows to a downstream water body. Isolated wetlands are not

necessarily small. They can be large systems with substantial heterogeneity and diverse habitat types (Tiner et al. 2002, Leibowitz 2003).

Generally, isolated wetlands provide most of the same functions as non-isolated wetlands and do so for the same reasons: position in the landscape, hydrologic regime, and type of soils and vegetation present (Leibowitz 2003, Whigam and Jordan 2003, Liebowitz and Nadeau 2003). Basic functions of isolated wetlands as described by Hruby et al. (1999), Tiner et al. (2002), Leibowitz (2003), and Whigam and Jordan (2003) are presented below.

- **Water quantity (hydrologic functions).** Isolated wetlands have no surface outlet. Precipitation and local runoff entering the wetland must either return to the atmosphere by evapotranspiration or infiltrate into groundwater (Leibowitz 2003). As a result, their ability to retain surface water may be significant, depending upon the surrounding topography. This provides potential flood storage because no surface water leaves the wetland to cause potential flooding or erosion downgradient.

- **Water quality.** Because they lack an outlet, isolated wetlands function as sediment traps for contaminants that move into them. Isolated wetlands function as sinks for most dissolved and all sediment-associated nutrients and toxics because they have no outlets that allow materials to be transported downgradient (Hruby et al. 1999). A review of the literature by Whigam and Jordan (2003) concludes that isolated, depressional wetlands have been shown to improve water quality and to efficiently retain nutrients.

- **Wildlife habitat.** Isolated wetlands provide wildlife habitat functions similar to those of non-isolated wetlands (Liebowitz 2003), except in regard to habitat for migrating fish in Washington (Hruby et al. 1999). The habitat value of isolated wetlands is governed by the same factors as non-isolated wetlands (hydrologic regime, vegetation, habitat structure, connectivity to other habitats, etc.) (Liebowitz 2003, Gibbons 2003). Tiner et al. (2002) found that isolated wetlands provide essential habitat for a wide range of guilds and may be vital to maintaining viable, genetically diverse metapopulations. They state:

  > *From an ecological standpoint, isolated wetlands are among the country's most significant biological resources. In some areas, isolation has led to the evolution of endemic species vital for the conservation of biodiversity. In other cases, their isolation and sheer numbers in a given locality have made these wetlands crucial habitats for amphibian breeding and survival (e.g., woodland vernal pools and cypress domes) or for waterfowl and waterbird breeding (e.g., potholes). In arid and semi-arid regions, many isolated wetlands are veritable oases – watering places and habitats vital to many wildlife that use them for breeding, feeding, and resting, or for their primary residence.*

5.3.5 Delineation Methods

In addition to the definition of what constitutes a wetland, the U.S. Army Corps of Engineers (Corps) and Washington State Department of Ecology (Ecology) have provided guidance on how to determine the edge of a wetland (i.e., how to delineate the wetland boundary). Delineating a wetland's boundary is a necessary step in the regulatory process because it factors into calculations of potential wetland impacts and determines the starting point for buffers and setbacks.

The Corps published a federal manual to delineate wetlands in 1987 and another manual in 1989, jointly with the U.S. Environmental Protection Agency (EPA), Soil Conservation Service, and U.S. Fish and Wildlife Service. In subsequent years (1991, 1992, and with EPA in 1994) the Corps released updates to clarify questions and provide regional guidance.

In the early 1990s, there was substantial controversy over proposals to change the 1987 and 1989 federal delineation manuals. A substantial amount of literature was produced analyzing the effectiveness of the various delineation manuals for determining a wetland edge. In subsequent years, the use of the 1987 Federal Manual for Delineation of Wetland Areas became the required legal standard for the Corps.

As required by state legislation, Ecology issued the *Washington State Wetlands Identification and Delineation Manual* in 1996 (WAC 173-22-080, Ecology publication #96-94). Ecology's manual uses the original 1987 Corps of Engineers manual and incorporates changes in the manual made by the federal government since 1987. The state manual includes national guidance issued by the Corps in 1991 and 1992 (which is not present in the 1987 Corps manual), as well as regional guidance issued by the Corps and EPA in 1994. In addition, the state manual eliminated references and examples that were not relevant to Washington State and added examples and situations relevant to Washington. The 1996 state manual is required by statute (RCW 36.70A.175) to be used by local jurisdictions in implementing the Growth Management Act. Since the two manuals rely upon the same criteria and indicators for hydrology, soils, and vegetation, proper use of either manual should result in the same boundary.

5.3.6 Summary of Key Points

- Regulatory agencies define the term *wetland* in slightly different ways.
- Local jurisdictions often differentiate between "biological wetlands" and "regulated wetlands". The distinction is often based on the wetland rating and/or wetland size.
- The studies of the correlation of wetland size to wildlife use conflict somewhat in their findings, but most generally conclude that small wetlands are important habitats (particularly where adjacent buffer habitats are available) and that elimination of small wetlands can negatively impact local populations.

- Small wetlands provide habitat for a range of species that are not a subset of the species found in larger, more permanently inundated wetlands. Small wetlands do not just provide a smaller area for the same array of amphibian species found in larger wetlands.

- Small wetlands are very important in reducing isolation among wetland habitat patches. Smaller wetlands provide significant habitat for wildlife and affect the habitat suitability of larger wetlands by reducing isolation on the landscape.

- The presence of small wetlands reduces the distance between wetlands and thus increases the probability of successful dispersal of organisms. This, in turn, likely increases the number of individuals dispersing among patches in a wetland mosaic, thereby reducing the chance of population extinction.

- Isolated wetlands provide the same range of wetland functions as non-isolated wetlands. Isolated wetlands provide important water quantity, water quality, and habitat functions.

- The U.S. Army Corps of Engineers 1987 wetland delineation manual and the 1996 *Washington State Wetlands Identification and Delineation Manual* are the current standards to be used in determining the boundary of a wetland. Correct use of these two manuals should result in the same wetland boundary.

5.4 Wetland Rating Systems

Wetland rating systems (or categorizations) are one of the numerous procedures that have been developed to analyze wetlands, providing ways to identify, characterize, or rate wetland characteristics, functions, and social benefits (values). Categorizations, as well as other procedures such as function assessment, are used by natural resource managers and regulators in a variety of contexts for regulating, planning, and managing the wetland resource (Bartoldus 1999). In the context of local regulations, rating systems are used to categorize wetlands based on different needs for protection. However, rating systems can often be used as one means to analyze wetlands.

Many different procedures to analyze wetlands have been developed in the last three decades. These range from detailed scientific evaluations that may require many years to complete, to the judgments of individual experts during one visit to a wetland. For example, Bartoldus (1999) summarized 40 different tools that were developed up to 1998, and that are used to meet the needs of regulating and managing wetlands.

Although many different rating-type tools have been developed, the literature search for this document did not uncover any analyses of the effectiveness of rating systems at protecting the wetland resource. It is assumed that better protection for wetlands is provided with improved understanding of wetland functions and values (e.g., Roth et al. 1993, National Research Council 1995).

Scientific rigor is often time consuming and costly. For regulatory use, tools are needed that provide some information on the functions and values of wetlands in a time- and cost-effective way. One way to accomplish this is with an analytical tool that categorizes wetlands by their important attributes or characteristics based on the collective judgment of regional experts. Categorization methods, such as rating systems, are relatively rapid but can still provide some scientific rigor (Hruby 1999).

The rapid method most commonly used for analyzing wetlands in eastern and western Washington has been Ecology's wetland rating systems (Ecology 1991, 1993, Hruby 2004a,b). This rating system or some modification of it has been incorporated in the wetland regulations of at least 20 counties in the state and many cities and towns as well (Chris Parsons, Washington State Department of Community, Trade and Economic Development (CTED), personal communications and survey 1999, data are available on request from CTED).

In the first editions of the Washington State wetland rating systems, the term *rating* was not used in a manner that is consistent with its definition in the dictionary, and this has caused some confusion. The method does not rate the wetland and generate a relative estimate of value (e.g., high, medium, low). Rather, it is a categorization of wetlands based on specific criteria, such as sensitivity to disturbance and rarity in the landscape.

The rating systems were designed to differentiate between wetlands based on their sensitivity to disturbance, their significance, their rarity, our ability to replace them, and the functions they provide. However, the rating systems were not intended to replace a full assessment that may be necessary to determine the levels of performance for numerous functions or to plan and monitor a compensatory mitigation project. As noted in the wetland rating system for eastern Washington:

> *The rating categories are intended to be used as the basis for developing standards for protecting and managing the wetlands to minimize further loss of their resource value. The management decisions that can be made based on the rating include the width of buffers necessary to protect the wetland from adjacent development, the ratios needed to compensate for impacts to the wetland, and permitted uses in the wetland.* (Hruby 2004a)

The rating systems for both eastern and western Washington have been revised by Ecology in conjunction with teams of wetland experts and local planners in each region who provided technical input and field testing. The goal of the revisions is to reflect the best and most current science on wetlands and how they function (using three broad groups of functions—hydrologic, water quality, and habitat) while maintaining rapidity and ease of use. You can access the rating systems for eastern and western Washington at the following web site: http://www.ecy.wa.gov/programs/sea/wetlan.html.

Wetland rating systems used in other parts of the nation

Categorization systems have also been used in other parts of the United States to manage wetlands. Other states have wetland categorizations as part of their wetland laws and rules, and other jurisdictions have used them to help manage wetlands for specific projects. For example:

Vermont adopted a law (10 VSA Chapter 37, Section (a) (7-9)) mandating that rules be adopted to identify Vermont's significant wetlands. The rules categorize wetlands into three classes of which the first two are considered "significant" (Vermont Department of Environmental Conservation 1999).

New Jersey has a wetland categorization included directly in its law (NJAC 7:7A). Criteria are provided for categorizing wetlands into (1) freshwater wetlands of exceptional resource value, (2) wetlands of ordinary resource value, and (3) wetlands of intermediate resource value.

New York has adopted rules that categorize wetlands into four categories based on ecological associations, hydrologic features, pollution control features, cover types, and distribution and location (6 NYCRR Part 664.5).

West Eugene, Oregon developed a method for a plan based on "needs for protection" (City of Eugene 2002).

North Carolina created a GIS-based system that characterizes the "significance" of wetlands based on several landscape and function-based criteria (Gainey and Roise 1998).

5.4.1 Other Characteristics Used for Rating

Some wetlands in Washington are categorized in the Washington State wetland rating systems based on important characteristics that are not specifically related to functions. These characteristics include rarity on the landscape, sensitivity to disturbance, and difficulty in restoring or creating such wetlands through mitigation efforts (Ecology 1991, Hruby 2004a,b). The wetland types that have been defined for eastern and western Washington are listed below. Some of the types are unique to either eastern or western Washington (e.g., Wetlands in coastal lagoons are unique to western Washington):

- Bogs
- Alkali wetlands
- Mature and old-growth forested wetlands
- Vernal pools
- Wetlands identified by the Washington State Department of Natural Resources as "Natural Heritage" wetlands"

- Wetlands in coastal lagoons
- Interdunal wetlands
- Estuarine wetlands

Each of these types is described in more detail below.

5.4.1.1 Bogs

Many of the scientific studies of bogs have been published in Europe and the northern parts of the United States, such as Minnesota and Maine. There has not been extensive research on bogs in Washington State. This summary of the literature is not intended to be a thorough synthesis but provides basic background information regarding characteristics of bogs requiring special consideration for management.

Predominance of Organic Soils

Bogs are peatlands (wetlands with organic soils) that have been classified according to their shape, chemistry, plant species, and vegetation structure (Gore 1983). The common factor in bogs is the presence of organic soils or peat, which result from the accumulation of poorly decomposed plant material. The optimum conditions for peat formation occur in cool, humid climates in a location with poorly drained soil.

The rate of peat accumulation is generally quite low, although it can vary with site-specific factors. Heathewaite and Gottlich (1993) report rates of accumulation ranging from 2 to 4 inches (5 to 10 cm) every 100 years. Durno (1961) lists a range of 0.5 to 4.3 inches (1.2 to 11 cm) accumulation every 100 years. In Washington, Rigg (1958) reports peat accumulation of 1 inch (2.5 cm) in 40 years for the west side of the Cascades and 1 inch in 50 years on the east side. Peat can be as little as 8 inches (20 cm) deep to over 45 feet (15 m) deep (Heathewaite and Gottlich 1993).

The three ways that peat is formed, described below, illustrate the lengthy process of peat and bog formation and help explain why bogs are almost impossible to recreate through compensatory mitigation (see below and in Chapter 6).

- In a **filled-lake sequence**, open water progresses to a sedge or moss community that gradually builds a mat over the water, evolving into a bog, bog forest, and then climax community (Conway 1949).
- **Paludification** occurs when bogs invade the surrounding forest. Sphagnum species cause a rise in the water table as peat layers compress and impede drainage (Heathewaite and Gottlich 1993).
- A **flow-through succession** occurs when surface flows are modified. Organic matter builds up to the point where surface flows are diverted around the peat mound. As it builds, the mound becomes isolated from groundwater, relying solely on precipitation as its water source (Klinger 1996).

Studies have shown, on the other hand, that many bogs remain very stable for thousands of years as a sphagnum moss/shrub community, even though succession to a forested community can occur (Klinger 1996).

Acidity and Poor Nutrients

Bogs have unusual hydrodynamics and chemistry for wetlands. They typically only receive precipitation and very localized surface runoff as their sources of water. As a result, many essential nutrients, such as nitrogen, occur in low concentrations. The upper layers of peat, formed by slowly decomposing sphagnum, are often strongly acidic, usually with a pH of 4 or less.

Bogs typically support plant species that are specially adapted to these harsh growing conditions. Sphagnum moss, as well as other mosses, usually dominate the vegetation near the ground. Ericaceous shrubs, such as Labrador tea (*Ledum gladulosum*), are also common in bogs.

Trees can grow in bogs but at a very slow rate due to the poor growing conditions. In studies in the Pacific Northwest, Rigg (1918) found tree growth in sphagnum peat soils was slow. Rigg determined that hemlock (*Tsuga heterophylla*) grew in sphagnum soils at a rate that was only 27% of its growth rate in productive upland soils, and that Douglas-fir (*Pseudotsuga menziesii*) grew in sphagnum at only 16% of its growth rate in upland soils. He measured the annual growth of western red cedar (*Thuja plicata*) as only 0.02 inches (0.6 mm).

Although persistent wet conditions, low soil oxygen, and high acidity are important factors, it is actually the lack of available nutrients, or the inability of plants to absorb nutrients because of acidity (Moore and Bellamy 1974), that most influences the flora of bogs. Most bog species have developed special adaptations to these conditions and out-compete more common wetland plants (Mitsch and Gosselink 2000). Therefore, this makes bog species susceptible to nutrient loading and changes in acidity (as well as alterations in water source that can precipitate these changes) that would enable other species to establish and dominate.

Bogs in Western and Eastern Washington

In western Washington, Kunze (1994) characterized numerous types of peatlands, including bogs and fens. She identified 10 types of sphagnum bog communities in the Puget Trough region and 14 in the Olympic Peninsula/southwest Washington. They occur in the lowlands of the Puget Trough in depressions, oxbows, and old lake beds. These typically have a raised center with a moat around the edge. Bogs and fens also occur on the Olympic Peninsula and in southwest Washington where they can occupy basins, slopes, and flat to rolling ground, as well as forming along low-gradient streams. Bogs in the foothills of the Cascades include sloping bogs, which are influenced by both mineral soil water and precipitation.

Peatlands in eastern Washington have not been classified to the extent of those in western Washington. However, 50 peatlands were identified by Rigg (1958). Forty-four of those

identified were located in the northeastern corner of the state. They included fens associated with flowing water, and bogs formed in depressions or along lake margins. Six peat systems were found in scabland channels and depressions on the Columbia Plateau.

Difficulty in Restoring Bogs

Researchers in Northern Europe and Canada have found that restoring bogs is difficult, specifically in regard to plant communities (Bolscher 1995, Grosvermier et al. 1995, Schouwenaars 1995, Schrautzer et al. 1996), water regime (Grootjans and van Diggelen 1995, Schouwenaars 1995), and/or water chemistry (Wind-Mulder and Vitt 2000). In fact, restoration may be impossible because of changes to the biotic and abiotic properties (Shouwenaars 1995, Schrautzer et al. 1996).

It is apparent that true restoration of a raised bog ecosystem is a long-term process. In *Restoration of Temperate Wetlands*, Joosten (1995) states:

> *Long term studies in bog regeneration indicate that restoration of bogs as self-regulating landscapes after severe anthropogenic damage is impossible within human time perspective, because the necessary massive re-establishment of bog key species and renewed accumulation of peat require centuries.*

Refer to Chapter 6 for more information on the challenges in restoring bogs.

5.4.1.2 Alkali Wetlands

Alkali wetlands are characterized by the occurrence of non-tidal, shallow saline water. In eastern Washington, these wetlands contain surface water with specific conductance (a measure of salinity) that exceeds 3,000 micromhos per centimeter. These wetlands provide the primary habitat for several species of migratory shorebirds and are also heavily used by migrating waterfowl. They also have unique plants and animals that are not found anywhere else in eastern Washington. For example, the small alkali bee that is used to pollinate alfalfa and onion for seed production lives in alkali systems. This bee is a valuable natural resource for agriculture in the western United States and especially in eastern Washington (Delaplane and Mayer 2000). The "regular" bees which pollinate fruits and vegetables are generally too large to pollinate the small flowers of these commercially important plants.

The salt concentrations in alkali wetlands have resulted from a relatively long-term process of groundwater surfacing and evaporating. These conditions cannot be easily reproduced through compensatory mitigation because the balance of salts, evaporation, and water inflows is hard to reproduce, and no references were found suggesting this has ever been attempted. Alkali wetlands are also rare in the landscape of eastern Washington. Of several hundred wetlands that were surveyed and visited by wetland scientists during field work for the state's function assessment methods and the rating system for eastern Washington (Hruby et al. 2000, Hruby 2004a), only nine could be classified as alkali.

5.4.1.3 Mature and Old-Growth Forested Wetlands

No mature or old-growth forested wetlands have ever been successfully created or restored through compensatory mitigation. A mature forested wetland may require 80 years or more to develop, and the full range of functions performed by these wetlands may take even longer (Stanturf et al. 2001). The actual time required to reconstruct old-growth forests and their soil properties (in contrast to mature forests) is unknown (Zedler and Callaway 1999). These forested wetlands provide important functions associated with wetlands as well as habitat functions associated with mature and old-growth forests. (Washington State Department of Fish and Wildlife 1999a).

5.4.1.4 Vernal Pools

Vernal pool wetlands occur in eastern Washington and are formed when small depressions in bedrock or in shallow soils fill with snowmelt or spring rains. They retain water until the late spring when reduced precipitation and increased evapotranspiration lead to a complete drying out. The wetlands hold water long enough throughout the year to allow some strictly aquatic organisms to flourish but not long enough for the development of a typical wetland environment (Zedler 1987). Vernal pools often contain upland species during the summer after they dry out and may be difficult to identify as jurisdictional wetlands during part of the year.

Vernal pools in the scablands are the first to melt in the early spring. This open water provides areas where migrating waterfowl can find food while other, larger bodies of water are still frozen. Furthermore, the open water provides areas for pair bonding of waterfowl (R. Friesz, Washington State Department of Fish and Wildlife, personal communications 2000-2004). Thus, vernal pools in a landscape with other wetlands provide a critical habitat function for waterfowl (Hruby 2004a).

5.4.1.5 "Natural Heritage" Wetlands

"Natural Heritage" wetlands are those that have been identified by scientists of the Washington State Natural Heritage Program as high-quality, relatively undisturbed wetlands, and wetlands that support state threatened, endangered, or sensitive plant species.

The Natural Heritage Program has identified important natural plant communities and species that are very sensitive to disturbance or threatened by human activities and maintains a database of these sites. The program's web site states:

> *Some natural systems and species will survive in Washington only if we give them special attention. By focusing on species at risk and maintaining the diversity of natural ecosystems and native species, we can help assure our state's continued environmental and economic health.* (Washington State Department of Natural Resources No Date, http://www.dnr.wa.gov/nhp/about.html)

5.4.1.6 Estuarine Wetlands

Estuaries, the areas where freshwater and salt water mix, are among the most highly productive and complex ecosystems. Here, tremendous quantities of sediments, nutrients, and organic matter are exchanged between terrestrial, freshwater, and marine communities. A large number of plants and animals benefit from estuarine wetlands. Fish, shellfish, birds, and plants are the most visible organisms that live in estuarine wetlands. However, a huge variety of other life forms also live in an estuarine wetland, including many kinds of diatoms, algae and invertebrates.

Estuaries, of which estuarine wetlands are a part, are a "priority habitat" as defined by the state Department of Fish and Wildlife. Estuaries have a high fish and wildlife density and species richness, important breeding habitat, important fish and wildlife seasonal ranges and movement corridors, limited availability, and high vulnerability to alteration of their habitat (Washington State Department of Fish and Wildlife, http://www.wa.gov/wdfw/hab/phslist.htm , accessed October 15, 2003).

Estuarine wetlands are not freshwater wetlands, and therefore, information about them was not reviewed in Volume 1. They are included in this compilation of wetlands with special characteristics because they are included in the wetland rating System for western Washington (Hruby 2004b). They are often found adjacent to freshwater wetlands and should be managed in conjunction with freshwater wetlands. The methods for identifying estuarine wetlands and the rationale for protecting them are described in more detail in the rating system (Hruby 2004b).

5.4.1.7 Wetlands in Coastal Lagoons

Coastal lagoons are shallow bodies of water, like a pond, partly or completely separated from the sea by a barrier beach. They may, or may not, be connected to the sea by an inlet, but they all receive periodic influxes of salt water. This can be either through storm surges overtopping the barrier beach or by flow through the porous sediments of the beach. Coastal lagoons often contain vegetated areas that are jurisdictional wetlands. The wetlands associated with coastal lagoons are, therefore, included in the rating system as wetlands with special characteristics.

Wetlands in coastal lagoons probably cannot be reproduced through compensatory mitigation, and they are relatively rare in the landscape. No information was found on any attempts to create or restore wetlands in coastal lagoons in Washington that would suggest this type of compensatory mitigation is possible. Any impacts to lagoons will, therefore, probably result in a net loss of their functions and values.

In addition, coastal lagoons and their associated wetlands are proving to be very important habitat for salmonids. Unpublished reports of ongoing research in the Puget Sound (Hirschi et al. 2003, Beamer et al. 2003) suggest coastal lagoons are heavily used by juvenile salmonids.

5.4.1.8 Interdunal Wetlands

As defined in the western Washington rating system (Hruby 2004b), any wetlands that are located to the west of the Boundary Line of Upland Ownership as determined in 1889 are considered interdunal. The boundary line is a legally defined line along the Pacific Coast. Interdunal wetlands form in the "deflation plains" and "swales" that are geomorphic features in areas of coastal dunes. These dunes are the result of the interaction between sand, wind, water, and plants. The dune system immediately behind the ocean beach (the primary dune system) and its associated wetlands is very dynamic and can change from storm to storm (Wiedemann 1984). This means that the location of the wetlands is not fixed and may change from year to year.

Interdunal wetlands provide critical habitat for many species in this ecosystem (Wiedemann 1984). Although important, these wetlands constitute only a small part of the total dune system (Wiedemann 1984). No methods have been developed to characterize how well interdunal wetlands function so these wetlands cannot be rated by a score for their functions. In the absence of direct methods for characterizing their functions, the rating of interdunal wetlands is based on their documented importance as habitat in the coastal dune ecosystem.

5.4.2 Summary of Key Points

- Wetland rating systems provide a rapid method to identify, characterize, categorize, or estimate relative wetland functions and values. This information is used in regulating and managing wetlands.

- The rapid method most commonly used for analyzing wetlands in eastern and western Washington has been the Washington State wetland rating systems. The rating system was designed to differentiate between wetlands based on a broad grouping of functions that they provide (hydrologic, water quality, and habitat), as well as other characteristics (listed in the next bullet). However, this rating system does not replace the more robust function assessment methods developed for Washington State. The latter may be necessary to determine the level of performance for specific functions (such as the potential to remove sediment) or to plan and monitor a compensatory mitigation project.

- In the rating system, some wetlands are categorized because of their rarity on the landscape, sensitivity to disturbance, or difficulty in restoration or creation through mitigation efforts, and not because of the functions these wetlands perform. The wetland types in Washington that are included in the rating system because they have these other characteristics include bogs, alkali wetlands, mature and old-growth forested wetlands, vernal pools, estuarine wetlands, wetlands in coastal lagoons, interdunal wetlands, and "Natural Heritage" wetlands.

5.5 Buffers

Buffers are another common element of wetland regulations. Buffers are vegetated areas adjacent to an aquatic resource that can, through various physical, chemical, and/or biological processes, reduce impacts from adjacent land uses. Buffers also provide the terrestrial habitats necessary for wildlife that use wetlands to meet their life-history needs. In this document, we collectively call these processes that buffers provide the *functions* of buffers. Buffers and other adjacent upland areas provide habitat for other wildlife species that do not commonly use wetlands. This document does not address those functions of upland habitats.

The primary purpose of buffers is to protect and maintain the wide variety of functions and values provided by wetlands (or other aquatic areas). The physical characteristics of buffers—slope, soils, vegetation, and width—determine how well buffers reduce the adverse impacts of human development and provide the habitat needed by wildlife species that use wetlands. These characteristics are discussed in detail in this section.

The subject of buffers is well documented in the scientific literature. The research on buffers has occurred worldwide, and this section includes literature from a variety of regions when it was found to be relevant. In particular, a variety of literature related to agricultural practices and vegetated filter strips from the north-central United States and south-central Canada is directly relevant to some agricultural practices in Washington State, especially east of the Cascades. In addition, studies on buffers in urban and suburban settings conducted in the Pacific Northwest region are clearly relevant. However, many of the buffer studies conducted elsewhere in the U.S. and the world, as well as the many buffer synthesis documents, provide information relevant to the state of Washington.

The majority of research on buffers tends to focus on the processes that buffers provide to filter sediment or take up nutrients (i.e., their influence on water quality). Far fewer studies look at the influence of a buffer's physical characteristics on attenuating surface water flow rates, except as it relates to water quality. The long-term effectiveness of buffers in providing such mechanical and biological processes is not well documented in the literature and may represent a critical need for future research.

The literature on buffers related to wildlife is, in general, less focused. Most studies document the needs of a particular species or guild relative to distances for breeding or other life-history needs within a radius from aquatic habitats. There is substantial literature on the implications of habitat fragmentation and connectivity, some of it related specifically to agricultural practices, forestry practices, or the impacts of urbanization. This literature does not specifically address the role of buffers in providing connectivity between wetlands and other parts of the landscape. It does, however, unequivocally support maintaining connectivity between wetlands in order to maintain viable populations of species that are closely associated with wetlands. The reader is referred to Section 4.11 in Chapter 4, which discussed the effects of habitat loss and fragmentation as well as Section 5.5.4.3.

Older research studied the tolerance limits of wetland wildlife for disturbance—how closely a disturbance can approach animals before they are flushed from wetlands—with particular emphasis on waterfowl. These studies tend to be older than 1990 and focus on the prairie pothole region of North America. Where the findings are germane and where they have not been superceded by more recent work, they are included.

In addition to papers on specific research studies, multiple compilations and syntheses of literature on buffers have been completed since 1990. Synthesis papers were compiled by Castelle and other authors (1992b, 1994, and 2000) and another was compiled by McMillan (2000) as a master's thesis. These compilations include literature that was published prior to 1990, but much of the work they rely on is considered seminal to the effectiveness of buffers in protecting wetlands and contributing to habitat. Therefore these synthesis documents are used in this document as direct sources when no more recent research was found to supercede the earlier findings.

This section also cites literature related to stream buffers and riparian areas when the findings are relevant to the influence these areas have on the adjacent aquatic resource. The literature on stream buffers related to microclimate, water quality influences, and some habitat characteristics is particularly relevant because the ways buffers protect and maintain these functions is similar whether they are adjacent to streams or wetlands.

5.5.1 Terms Used to Describe Buffers

The scientific literature varies widely on the terms used to denote the area that serves to reduce impacts to wetlands from adjacent land uses and provide habitat for parts of the life-cycle of many species. Common terms include:

- Buffer
- Wetland setback
- Vegetated filter strip
- Buffer strip
- Riparian area
- Riparian zone
- Riparian corridor

These terms can be differentiated as those that are a product of regulations or policy language and those that define or describe an ecological condition or location (Castelle et al. 1994). Terms such as *buffer*, *wetland setback*, or *vegetated filter strip* are most commonly applied in an administrative context to denote the landscape immediately adjacent to an aquatic resource, the dimensions of which are legally determined. The terms *buffer strip* or *vegetated filter strip* may imply a relatively undisturbed, vegetated

area that helps attenuate the adverse effects of land uses adjacent to a wetland. For example, Norman (1996) provides this definition:

> *Buffer strips are strips of vegetated land composed in many cases of natural ecotonal and upland plant communities which separate development from environmentally sensitive areas and lessen these adverse impacts of human disturbance.*

The terms *riparian areas* or *riparian zones* are defined by many to denote ecologically discernable ecotones (transition zones) along aquatic resources where the presence or action of surface waters, or the presence and duration of shallow groundwater, influences the structure and composition of the vegetation community (Lowrance et al. 1995, Harper and MacDonald 2001). The term *riparian corridor* is defined by Naiman et al. (1993) as "encompass(ing) the stream channel and that portion of the terrestrial landscape from the high water mark towards the uplands where vegetation may be influenced by elevated water tables or flooding, and by the ability of the soils to hold water."

5.5.2 Functions Provided by Buffers

The literature is broadly consistent on the ways in which buffers can provide for the protection and maintenance of wetland functions. These include:

- Removing sediment
- Removing excess nutrients (phosphorous and nitrogen)
- Removing toxics (bacteria, metals, pesticides)
- Influencing the microclimate
- Maintaining adjacent habitat critical for the life needs of many species that use wetlands
- Screening adjacent disturbances (noise, light, etc.)
- Maintaining habitat connectivity

As noted by Castelle and Johnson (2000), buffers can be both ecological sources and sinks. They can control or limit the effects of land uses upslope of the aquatic resource (act as a sink), and they can contribute biological benefits to the aquatic resource (act as a source). Naimen et al. (1992) summarize the range of functions provided by buffers along streams as follows:

> *It is well known that riparian vegetation regulates light and temperature regimes, provides nourishment to aquatic as well as terrestrial biota, acts as a source of large woody debris,…regulates the flow of water and nutrients from uplands to the stream, and maintains biodiversity by providing an unusually diverse array of habitat and ecological services.*

These same functions can be attributed to wetland buffers (Castelle et al. 1992b, Desbonnet et al. 1994, McMillan 2000).

The literature also describes the physical, chemical, and/or biological characteristics of a buffer that determine the functions it provides. The most frequently cited physical characteristics that influence the effectiveness of a buffer are:

- Vegetation characteristics (composition, density, and roughness—for example, downed material)
- Percent slope
- Soils
- Buffer width and length (adjacent to the source of impacts)

Only two of the physical characteristics noted above can be easily managed (vegetation characteristics and buffer width/length), while the others are characteristics that do not lend themselves to manipulation.

By far the issue of greatest interest with respect to buffers is the question of how wide a buffer needs to be in order to be effective in protecting a wetland (or other aquatic resource). While the literature is unanimous that buffers provide important functions that protect wetlands and provide essential habitat for many species, there is wide-ranging discussion about how much buffer is necessary to be effective in providing a particular level of function (Young et al. 1980, Booth 1991, Castelle et al. 1994, Norman 1996, Dosskey 2000, McMillan 2000, Rickerl et al. 2000).

For ease of discussion as to the effective widths of buffers, the functions of buffers listed above are grouped into two major categories:

- Water quality (discussed in Section 5.5.3)
- Wildlife habitat (discussed in Section 5.5.4)

Buffers and their influence on wetland hydroperiod, as described in the few studies found on this subject, are summarized in the shaded box on the next page.

The following literature sources are generally consistent in describing what functions buffers provide to aquatic resources as well as the physical parameters that influence a buffer's ability to provide these functions: Budd et al. (1987), Phillips (1989), Castelle et al. (1992, 1994), Naiman et al. (1992), Belt and O'Laughlin (1994), Desbonnet et al. (1994), Norman (1996), Dillaha and Inamdar (1997), Dosskey (2000), Van der Kamp and Hayashi (1998), Liquori (2000), McMillan (2000), Todd (2000), Townsend and Robinson (2001), Dosskey (2001).

Buffers alone have limited influence on wetland hydroperiod

As described in detail in Chapter 3, human land uses, such as agricultural practices, clearing, and land development, alter the movement and storage of surface water and groundwater within a wetland's contributing basin. These changes can significantly affect the hydroperiod of wetlands and other aquatic resources, causing an adverse effect on many wetland functions (Azous and Horner 2001). There is little published literature on the effectiveness of buffers in ameliorating the effect of changes in land use within the contributing basin on wetland hydroperiod. Some of the literature indicates that wetland buffers are far less effective at maintaining wetland hydroperiod than other mechanisms, such as controlling impervious surfaces and utilizing effective stormwater management practices (Herson-Jones et al. 1995).

Research in the Puget Sound Basin has agreed that changes in the land cover type in the contributing basin have a stronger influence on the resulting hydroperiod of the wetland than the buffer does (Booth 1991, Azous and Horner 2001). An exception may be for wetlands that have a very small contributing basin. However, the rate and manner in which stormwater enters the wetland following land-use changes in the contributing basin will most often shift from sheet flow and interflow to one or more point sources, resulting in a potential change in hydroperiod. Based on hydroperiod models using the U.S. Environmental Protection Agency's Hydrologic Simulation Program Fortran (HSPF model) for areas west of the Cascades, the wetland will tend to receive more water more quickly in the fall and will receive less water for a shorter period in the spring, resulting in a shift in the seasonal hydroperiod.

Buffer width is usually not sufficient to counteract the influence of land-use changes and stormwater management facilities within the wetland's contributing basin.

5.5.3 Buffers and Protection of Water Quality

Buffers protect the water quality of wetlands through four basic mechanisms:

- They remove sediment (and attached pollutants) from surface water flowing across the buffer
- They biologically "treat" surface and shallow groundwater through plant uptake or by biological conversion of nutrients and bacteria into less harmful forms
- They bind dissolved pollutants by adsorption onto clay and humus particles in the soil
- They help maintain the water temperatures in the wetland through shading and blocking wind

Literature describing the different ways that buffers maintain and improve water quality in wetlands and other aquatic areas is abundant. There is also considerable research on the effective widths that provide a relative percentage of removal of sediments, nutrients, and some toxics emanating from various sources. Four categories of water quality improvement are discussed below:

- Removing sediment
- Removing nutrients
- Removing toxics and pathogens
- Maintaining microclimate

For each of these categories, a summary is provided on what the literature says about the relationship between buffer width (or other characteristics) and the buffer's effectiveness in providing that type of water quality improvement. A summary table is included that lists the range of buffer widths for each category and the literature references that substantiate those findings. However, the literature does not address the issue of "how much pollutant removal is acceptable." For each pollutant, there may be a maximum amount that a buffer can process before its ability to do so is overwhelmed. The literature does not provide any specific thresholds (See section 5.5.5.3 for more on this issue).

5.5.3.1 Removing Sediment

Characteristics that Influence a Buffer's Ability to Remove Sediment

A buffer's ability to remove sediment from surface water flows depends upon several physical characteristics of the buffer. Sediment removal occurs when (Castelle et al. 1992b, Dillaha and Inamdar 1997, Phillips 1989):

- Flows are slowed sufficiently to allow particles to settle out
- Physical filtering by vegetation and roots mechanically removes sediments from the water column
- The slope of the buffer is of a low enough gradient to preclude formation of rills and scouring
- There is large woody debris on the ground to create roughness
- The infiltration rate of the soils allows water to move through the soils rather than on the surface

The way sediment-laden water enters a buffer influences the ability of the buffer to slow the flows sufficiently to allow sediment deposition. Several studies noted that vegetated buffers are only effective at removing sediments if sediment-laden waters enter the buffer as sheet flow, rather than in channels or rivulets (Phillips 1989, Booth 1991, Castelle et

al. 1992b, Desbonnet et al. 1994, Belt and O'Laughlin 1994, Sheridan et al. 1999). Norman (1996) cites work conducted by Schueler in 1987 that found buffers in urban settings were most effective at removing sediments where slopes were less than 5%, and waters entered the buffer in shallow, dispersed sheet flow. Norman surmised that, "The rate of removal of pollutants appears to be a function of the width, slope, and soil permeability of the (buffer) strip, the size of the contributing runoff area, and the runoff velocity."

In other research, Sheridan et al. (1999) found that the greatest reduction in sediment loading occurs in the initial "treatment" stages using a vegetated filter strip that is managed and mowed. Their research found the greatest removal of sediments (56 to 72%) and reduction in flow rates occurs in the outer portion of a vegetated filter strip (the strip closest to the source of sediment). Grass filter strips provided removal ranging from 78 to 83% of suspended sediments.

The ability of a buffer to provide physical filtering of sediments also depends on the condition of the vegetation and the surface roughness. Belt and O'Laughlin (1994) noted that when vegetation, rocks, or other obstructions were eliminated from the buffer surface, sediment-laden waters flowed further into (or through) a buffer. Buffers were found to be effective in removing sediments only if flows were shallow and broad, not narrow and incised. The presence of woody debris and vegetative obstructions on the ground surface (roughness) was found to slow flows, inhibit the formation of rills, and facilitate sediment deposition.

In contrast, hydrologic models created by Phillips (1989) estimated that surface roughness would be of minor concern, and buffer width was not critical, as long as a minimum 49-foot (15 m) buffer was maintained. This study was based on estimated models, whereas Belt and O'Laughlin's work was based on field measurements.

Phillips (1989) also emphasized the importance of slope. He states, "Results show that where solid-phase pollutants transported as suspended or bed-load in overland flow are the major concern, slope gradient is the most critical factor, followed by soil hydraulic conductivity." Slope gradient is critical because, on slopes greater than 5%, sheet flow can start to become channelized. Channelized flows have faster rates, more erosive powers, and less contact with vegetation (Norman 1996). Faster moving water has the capacity to carry fine sediment particles farther than slower flows, even moving through dense vegetation.

In his research in urbanizing settings, Booth (1991) notes that buffers adjacent to aquatic resources may have limited ability to filter and slow flows caused by stormwater. He found that (1) in some instances the buffers no longer existed in a natural vegetated condition, (2) once development occurred, and the buffer was subdivided into multiple private ownerships, maintaining an intact buffer was not possible, or (3) the increased volumes and rates of flows were too significant to be controlled by conditions within a vegetated buffer.

Buffers were found to facilitate reduction of sediment from active agricultural fields in several studies:

- Welsch (1991) found that a three-tiered buffer system on a shallow slope, with the first tier (closest to the source of sediment) composed of dense herbaceous vegetation, maximized sediment removal (See Section 5.5.6 for a discussion of the three-tiered system).
- Dosskey (2001) noted in agricultural settings that vegetated buffers retain pollutants by reducing the flow rates and filtering surface runoff from fields.
- Assessing management options to control non-point-source pollution (sediment, nitrogen, and phosphorus) in agricultural settings, Yocom et al. (1989) recommended the use of vegetated filter strips between actively cropped land and adjacent wetlands.

Buffer Width and Effectiveness in Removing Sediment

As noted above, the ability of a buffer to remove sediment is based on the condition of the buffer and its slope, as well as the characteristics of the incoming sediment. The following variables all contribute to the sediment removal effectiveness of a buffer:

- The velocity of sediment transport (in surface water)
- The size of sediment particles from the source materials
- The density of the vegetation present
- The presence and extent of large woody debris
- Surface roughness within the buffer

However, the relationship between the width of the buffer and its effectiveness is non-linear. The largest particles and the greatest percentage of particles are dropped in the outer portions of the buffer (closest to the source of sediment). In these outer areas, the rate of surface flow begins to diminish as the water is slowed by vegetation and woody debris. Slower water movement allows particles to drop out of the water column.

This is graphically illustrated in the graph below (Figure 5-1). This table is included here for illustrative purposes only, to depict the non-linear nature of buffers in removing sediments. This graph is based on data from the buffer synthesis by Desbonnet et al. (1994).

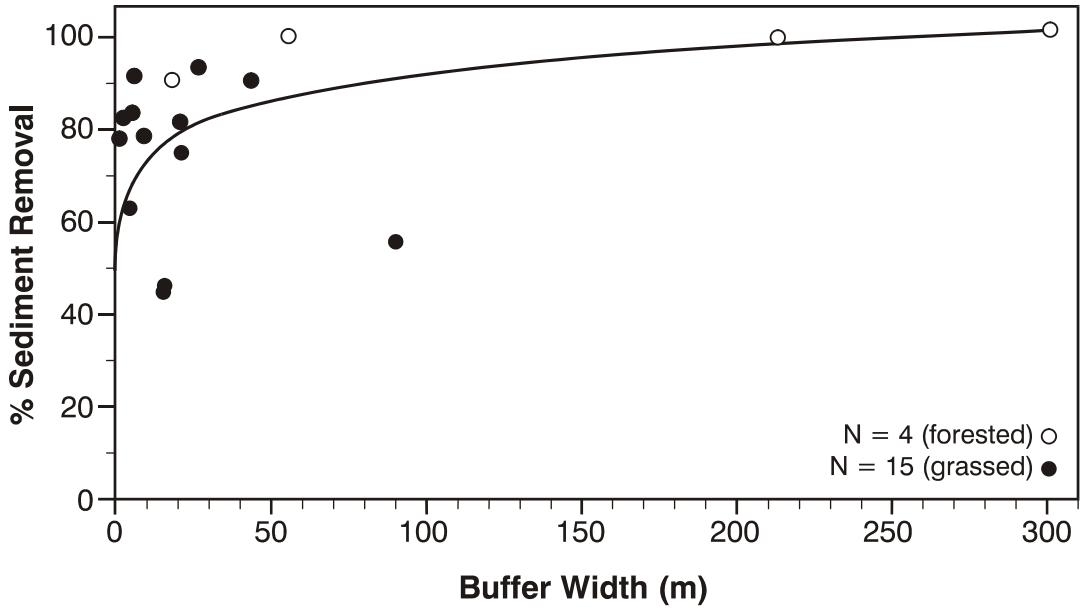

Figure 5-1. Relationship of percent removal to buffer width for the treatment of sediments contained in surface water runoff (Desbonnet et al. 1994).

In 1982, Wong and McCuen derived a formula to model a buffer's ability to remove sediments based on sediment particle size, the slope within the buffer, the rate of surface runoff, and the amount of vegetation and woody debris (roughness) in the buffer (Castelle et al. 1994). The model predicted that there would be a point of relative diminishing returns for function vs. width. For example, "If the sediment removal design criteria were increased from 90 to 95% on a 2% slope, then the buffer widths would have to be doubled from 30.5 to 61 m (100 to 200 ft)." In other words, the model predicted that the width of the buffer would have to double to achieve an additional 5% removal of sediment after 90% of it had already been removed from the water column. Desbonnet et al. (1994) determined that a small buffer (7 feet [2 m]) could effectively remove up to 60% of suspended sediment, while a buffer of up to 82 feet (25 m) would be needed to remove 80%.

These findings are consistent with others who have found that progressively larger buffer dimensions are required to filter out finer particles (Norman 1996). These and other studies are summarized in Table 5-1.

See Section 5.5.5 for discussion of the ability of buffers to continue providing sediment removal over the long term.

Table 5-1. Summary of studies on sediment control provided by buffers of various widths.

Author(s)	Date	Buffer Width	Comments
Broderson	1973	200 feet (61 m)	Effective sediment control "even on steep slopes"
Desbonnet et al.	1994	6.6 – 82 feet (2 – 25 m)	60% removal in 6.6 feet (2 m); 80% removal required 80 feet (25 m)
Desbonnet et al.	1994	16 – 49 feet (5 – 15 m)	On grassy buffers on slopes with less than 5% slope, removed all but the finest particles
Ghaffarzadeh et al.	1992	16 – 49 feet (5 – 15 m)	Found 85% removal in 30-foot (9.1 m) buffers
Horner and Mar	1982	200 feet (61 m)	80% of sediments. As cited by Castelle and Johnson (2000)
Lynch et al.	1985	98 feet (30 m)	75 to 80% removal of sediment from logging activities into wetlands
Norman	1996	9.8 feet (3 m): sands 49.9 feet (15.2 m): silts 400 feet (122 m): clays	Distances required for effective removal of progressively smaller particle sizes
Wong and McCuen	1982	100 – 200 feet (30.5 – 61 m)	90% at 100 feet (30 m), need 200 feet (61 m) to obtain 95% removal effectiveness
Young et al.	1980	80 feet (24.4 m)	92% sediment removal rate from feedlot through vegetated buffer strip

5.5.3.2 Removing Nutrients

Characteristics that Influence a Buffer's Ability to Remove Nutrients

Nutrients are transported into wetlands via sediment-laden water or dissolved in surface or shallow subsurface flows. The primary nutrients of concern are nitrogen and phosphorous. Buffers remove nitrogen and phosphorous through a variety of mechanisms that are similar to the mechanisms present within the wetland itself, as described in Chapter 2.

As much as 85% of phosphorous in surface waters is bound to sediments (Karr and Schlosser 1977) and thus can be removed via sediment removal in buffers. Phosphorus and other nutrients may be effectively reduced in surface waters by filtering and uptake; however, dissolved forms of nitrogen are not affected by surface processes and can be more effectively removed in the buffer through subsurface contact with fine roots (Muscutt et al. 1993, Townsend and Robinson 2001). Lowrance et al. (1995) confirm that the areas where improvements in water quality are the most effective are where precipitation moves across, through, or near the rooting zone of a forested buffer. These

findings are similar to those of Phillips (1989), who found that longer contact of dissolved pollutants through wider vegetated buffers was the most important factor for effective removal.

Buffer Width and Effectiveness in Removing Nutrients

It is difficult to compare studies of buffer width and effectiveness at removing nutrients because the basic parameters of the studies differ greatly. Some studies were conducted in field settings while others occurred in experimentally designed plots. There were differences in the loading rate of nutrients, the types of soils, and the vegetation in the buffers. Some studies examined only nitrogen or phosphorous removal, whereas others combined different nutrients. The result is that reported effectiveness of buffer widths for removing nutrients ranges from a few meters to hundreds of meters. Studies are listed in Table 5-2.

In a synthesis of research on nitrogen removal, McMillan (2000) found nitrogen can be effectively removed in buffer strips ranging from 20 to 98 feet (6 to 30 m) wide. He cites work by two research groups (Patty et al. 1997, Daniels and Gilliam 1996) that 47 to 99% removal of nitrogen can be achieved in buffers ranging from 20 to 66 feet (6 to 20 m) wide. This is not totally consistent with synthesis results presented by Desbonnet et al. (1994) that "well configured" buffers (with ideal slope, soils, and vegetation) as small as 30 feet (9 m) could reduce as much as 60% of nitrogen, while 197-foot (60 m) buffers would be necessary for 80% nitrogen removal.

A recent study from Oregon documented the role of red alder forests in exporting nitrogen to streams (Compton et al. 2003). They found that the percent of alder forest in a watershed was positively correlated with nitrate concentrations in surface water. This has implications for assuming that buffers with alder forests will help reduce the input of nitrogen from adjacent land uses into wetlands and other surface water.

The literature also describes a range of buffer widths necessary for phosphorus removal. Studies of buffer widths as small as 13 feet (4 m) and as large as 279 feet (85 m) found phosphorus removal rates of 50% to over 90% (see Table 5-2).

Overall, a consistent pattern emerges from the literature. The largest relative percent removal of phosphorus occurs within the outer portions of the buffer (closest to the source), while larger buffers are required to remove increasingly more of the nutrients. This consistency substantiates the conclusions of many that initial contact causes sediment-associated nutrients to be deposited, while dissolved nutrients require longer residence time and prolonged contact with vegetation for effective uptake (removal from the water column) to occur.

Castelle and Johnson (2000) surmised in their literature review that nutrient removal may have a similar non-linear relationship to buffer width as sediment removal. However, Phillips (1989) found that buffer width was a more critical element for dissolved nutrients (especially nitrogen), because wider buffers provided more prolonged contact with the rooting zone and time for uptake and conversion. Phillips did not report widths of buffers related to a certain percent of removal or effectiveness.

Limited research has been done on the long-term effectiveness of buffers for nutrient removal when there is an ongoing nutrient source present on the outside edge of the buffer. See Section 5.5.5.3 for a discussion.

Table 5-2. Summary of studies on nutrient removal provided by buffers of various widths.

Author(s)	Date	Width	Comments
Daniels and Gilliam	1996	20 – 66 feet (6 – 20 m)	47-99% removal of nitrogen
Desbonnet et al.	1994	30 feet (9 m): 60% removal 197 feet (60 m): 80% removal	Small buffers could have effective removal rates for nitrogen; much larger buffers are necessary for a significant increase in effectiveness
Desbonnet et al.	1994	Averages: 39 feet (12 m): 60% 279 feet (85 m): 80%	When all the findings from the literature synthesis were averaged, the average removal efficiencies were non-linear: larger buffers were needed for increases in effectiveness
Dillaha	1993	15 feet (4.6 m): 70% 30 feet (9.1 m): 84 %	Percent removal of suspended solids and their associated nutrients with vegetated filter strips. As cited in Todd (2000)
Dillaha	1993	15 feet (4.6 m): 61 % 30 feet (9.1 m): 79 %	Removal of phosphorus with vegetated filter strips. As cited by Todd (2000)
Dillaha	1993	15 feet (4.6 m): 54% 30 feet (9.1 m): 73%	Removal of nitrogen with vegetated filter strips. As cited by Todd (2000)
Doyle et al.	1977	12.5 feet (3.8 m) forested 13.1 feet (4 m) grass	Reduced nitrogen, phosphorus, and potassium levels
Edwards et al.	1983	98 feet (30 m)	50% removal rate of phosphorus
Lowrance	1992	23 feet (7 m)	Forested buffer zones were effective at removing nitrate through plant uptake and microbial denitrification
Lynch et al.	1985	98 feet (30 m)	Forested buffers reduced soluble nutrient levels from logging activities to "appropriate" levels
Patty et al.	1997	20 – 66 feet (6 – 20 m)	47 - 99% removal of nitrogen

5.5.3.3 Removing Toxics and Pathogens

Characteristics that Influence a Buffer's Ability to Remove Toxics and Pathogens

A buffer's ability to remove toxicants and pathogens is one of the least thoroughly studied. At this time, it represents a significant data gap. Castelle and Johnson (2000) note the lack of research on pathogens, toxicants and fecal coliform bacteria (an indicator of the possible presence of pathogens). Many of the studies they examined are quite old, but little recent research was found to supplement these older studies. Therefore, the conclusions presented from the synthesis of the previous work are provided here.

Gilliam (1994) also confirms in his work that little to no research is available on the effective removal of fecal coliforms or various pesticides. Much of the work assessed the effectiveness of removal of nutrients and toxics, without identifying a dimension of width necessary to provide that removal.

Toxics (pesticides and metals) can be removed by buffers through sedimentation, biological uptake by vegetation, adsorption onto clay or humus particles in the soil of the buffer, or degradation of the toxics through biochemical processes (McMillan 2000, Patty et al. 1997).

As mentioned in the discussion of sediment removal, Welsch (1991) described the use of a three-tier buffering system for the most effective removal of sediments and their associated toxics. The outermost tier (closest to the source of impacts) was a densely vegetated filter strip, managed to ensure no erosion or rill formation. He found the most effective removal of sediments and the toxics adhered to sediment particles was through surface sheet flows through the vegetated filter strip. The middle tier was subject to some management activities (limited agriculture or limited tree harvest), while the innermost tier was undisturbed natural vegetation. Dissolved nutrients and some toxics were not affected by physical filtering unless there was prolonged contact with the rooting zone through the shallow groundwater table. See Section 5.5.6 for further discussion.

Castelle and Johnson (2000) note that the apparent effectiveness of small buffers in removing toxics is due to the adsorption of many toxics to sediment particles. When vegetated buffers are effective at filtering sediments, they will also be effective at filtering those toxics and nutrients adhered to the sediments.

One study in Saskatchewan (Donald et al. 1999) found that the concentrations of agricultural pesticides and herbicides in wetlands were influenced by the timing of precipitation relative to the applications of the chemicals. They noted that buffer width may influence exposure of the wetland to these chemicals, but they did not quantify what buffer widths related to the effectiveness of removing chemicals.

Neary et al. (1993) reviewed studies in the Southeastern U.S. on the use of buffers in reducing contamination of water by pesticides. They found that cases of high concentrations of pesticides in water only occurred when no buffer was present or when pesticides were applied within the buffer. Regular use of buffer strips kept concentrations of pesticide residue within water-quality standards. Neary concluded that, generally speaking, buffer strips of 15 m (49 ft) or larger are effective in minimizing contamination of streams by pesticide residue.

Table 5-3 summarizes studies on the effectiveness of toxicant and pathogen removal provided by buffers of various widths.

Table 5-3. Summary of studies on pathogen control provided by buffers of various widths.

5.5.3.4 Maintaining Microclimate

The influence of buffers on microclimate is most often thought of in the context of shading for maintaining water temperature. This is well documented in the literature in relation to the effects on streams (Lynch et al. 1985, Johnson and Stypula 1993, Belt and O'Laughlin 1994, Castelle and Johnson 2000,). In those documents, literature focused on streams and their buffers is almost exclusively relied upon to discuss the influences of buffers on water temperature. No literature was found that specifically examined the influence of buffers on the water temperatures and microclimates within wetlands.

It may be tempting to deduce that the benefit of forested shade in moderating water temperatures is the same in wetlands as in streams. However, it is not reasonable to

apply to wetlands the findings on the widths used for stream buffers for the purpose of shading. As with streams, there are many variables that can influence how shading affects the water temperature in a wetland. These variables relate to differences in water budgets (e.g., the relative influence of groundwater on a seasonal basis, whether the wetland has an inlet/outlet, etc.). In addition, the physical configurations of a large open-water wetland, a small fully vegetated wetland, and a linear stream corridor may not provide reasonable parallels. With these limitations in mind, some relevant findings are provided below.

Forests can create shade and also block the wind, which can help moderate temperatures in adjacent aquatic systems (Oke 1987). Stable water temperature helps maintain water quality because cooler water can carry higher loads of dissolved oxygen, which is important for many aquatic biota. Warmer water can also result in a looser bond between sediment particles and nutrients, which could result in an increase in nutrient loading in warmer aquatic systems (Karr and Schlosser 1977).

Microclimate influences can also extend from large wetlands into the adjacent forests. Harper and MacDonald (2001) conducted research on boreal forests near lakes and found a "distinct lake edge community" of about 131 feet (40 m) width. The lake edge community tended to have greater structural diversity, less canopy cover, fewer snags, greater amounts of coarse woody debris, and greater number of saplings and mid-canopy trees than the interior forest. Changes in the distribution of vegetation species were along a shade tolerance gradient, but the authors postulated that moisture gradient or water table depth also had an influence. Their research was conducted within forests adjacent to open water lakes, but it would be valid to extrapolate their findings to forested communities adjacent to permanent, large open wetlands that would create the same "light and shade" effect. The findings imply that large open aquatic systems influence the adjoining upland community for approximately 131 feet (40 m) distance into the interior of the forested buffer. Thus, buffers not only influence temperatures and wind effects in a wetland, but research identifies that large aquatic systems may have a reverse positive influence on the vegetation structure and species diversity of the buffer. This can thereby affect some of the habitat discussed later in this chapter.

Table 5-4. Summary of a study on the influence of microclimate provided by buffers of various widths.

Author(s)	Date	Width	Comments
Harper and MacDonald	2001	Approx. 131 feet (40 m)	Influence of large aquatic systems on adjacent upland forest composition and structural complexity

5.5.3.5 Summary of Key Points

- The use of buffers to protect and maintain water quality in wetlands (removing sediments, nutrients, and toxicants) is best accomplished by ensuring sheet flow across a well vegetated buffer with a flat slope (less than 5%).

- Significant reductions in some pollutants, especially coarse sediments and the pollutants adhered to them, can be accomplished in a relatively narrow buffer of 16 to 66 feet (5 to 20 m), but removal of fine sediments requires substantially wider buffers of 66 to 328 feet (20 to 100 m).

- Removal of dissolved nutrients requires long retention times (dense vegetation and/or very low slope) and, more importantly, contact with fine roots in the upper soil profile (i.e., soils that are permeable and not compacted). Distances for dissolved nutrient removal are quite variable, ranging in the literature from approximately 16 to 131 feet (5 to 40 m).

- The literature is consistent in finding that it takes a proportionally larger buffer to remove significantly more pollutants because coarse sediments and the pollutants associated with them drop out in the initial (outer) portions of a buffer. It takes a longer time for settling, filtering, and contact with biologically active root zones to remove fine particles and dissolved nutrients.

- The role of buffers in protecting the microclimate of streams is well documented and may be applicable to wetlands, but no specific data on buffers and wetland microclimate maintenance were found.

5.5.4 Buffers and Wildlife Habitat

Wetland buffers are essential to maintaining viable wildlife habitat because they perform three overlapping functions:

- Buffers can provide an ecologically rich and diverse transition zone between aquatic and terrestrial habitats. This includes necessary terrestrial habitats for many wildlife species that use and/or need wetlands but also need terrestrial habitats to meet critical life requirements.

- Buffers can screen wetland habitat from the disturbances of adjacent human development

- Buffers may provide connectivity between otherwise isolated habitat areas

In regard to wildlife, most of the scientific research is not directly focused on the effectiveness of buffers for maintaining individuals or populations of species that use wetlands. Some of the research simply documents use of upland habitats adjacent to wetlands by wildlife to meet their life-history needs. For example, a substantial body of

research identifies the distances that amphibians may be found away from a wetland edge. However, the implications to amphibian populations of providing buffers that are smaller than those identified ranges are not well documented.

The following discussion summarizes the literature on buffers related to wildlife that use wetlands for the three essential functions listed above. Several documents are cited that represent a synthesis of scientific literature on the effectiveness of buffers for protecting wildlife-related functions of wetlands. Even though these documents include some research conducted prior to 1990, they have been included where relevant.

There is substantial literature on the implications to wildlife populations from fragmenting habitats as a result of human activities. However, this research was not necessarily conducted to address the effectiveness of various buffer widths. The literature on this topic is mentioned because of the management implications for the long-term viability of species that are closely associated with wetlands. The reader is referred to Section 4.11 in Chapter 4 and Section 5.5.4.3 for a detailed discussion of habitat fragmentation.

5.5.4.1 Maintaining Terrestrial Habitat Adjacent to Wetlands

Buffers provide a transition between aquatic and terrestrial environments and are a critical component of the habitat of wildlife that use wetlands. The specific habitat functions provided by wetland buffers include:

- Sites for wildlife for foraging, breeding, and nesting
- Cover for escape from predators or adverse weather
- Source of woody debris and organic matter that provides habitat structure and food, as well as moderation of water temperatures within adjacent wetlands to support species that are sensitive to temperature (e.g., fish, amphibians).
- Areas for dispersal and migration related to both individuals and populations; buffers may connect or be part of corridors

As defined previously, buffers are predominantly upland habitat communities that lie adjacent to aquatic habitats. They are a different habitat type than the wetland and their presence increases habitat heterogeneity by providing niches for more species. First described by Leopold (1933) as the "edge effect," and later by Odum (1959) as an "ecotone," this phenomenon features higher use of transition zones by wildlife, particularly between aquatic and terrestrial habitats. It has been demonstrated in studies of birds (Beecher 1942, McElveen 1977), mammals (Bider 1968), and amphibians (Bury 1988). The same pattern has been demonstrated in the Pacific Northwest in studies by Oakley et al. (1985), Knight (1988), and Cross (1988). Recent research conducted in the Puget Sound lowlands found that the greatest species richness of birds and small mammals in 50 foot wetland buffers was found when an additional 1,640 feet (500 m) of relatively undisturbed habitat was adjacent to the wetland buffer (Richter and Azous 2001b, 2001c).

Protection of upland areas adjacent to wetlands is critical to helping ensure that wildlife populations that are closely associated with wetlands have access to the habitat features necessary to meet their survival requirements. Species that are closely associated with wetlands, such as many amphibians, aquatic invertebrates, waterfowl, and some mammals, require access to wetlands for critical stages of their life-history. Many more species use wetlands, as well as other aquatic systems such as streams, lakes, or rivers, to meet various life-history needs. Research shows that species that were assumed to be dependent upon wetlands also depend upon adequate and appropriate upland habitats to maintain viable populations (Foster et al. 1984, Bury 1988, Washington Department of Wildlife in Castelle et al. 1992b, Semlitsch 1998, Semlitsch 2000).

In addition, vegetated buffers protect habitat in wetlands by maintaining the microclimate (through temperature moderation), as discussed previously, and by providing a source of organic matter to aquatic systems. This includes both large organic debris (e.g., logs, root wads, limbs), which provides habitat structure in aquatic environments, and particulate and dissolved organic matter, which provides a source of food for invertebrates (Brown 1985, Groffman et al. 1991a).

In coastal wetlands in South Carolina, Braccia and Batzer (2001) found that large woody debris within wetlands was critical for both aquatic and terrestrial invertebrate populations. They identified that the source of the large woody debris within the wetlands was from the adjacent uplands. The forest conditions in adjacent uplands, therefore, can have a significant influence on wetland biota because the aquatic invertebrates form the foundation of many food chains in aquatic settings (Castelle et al. 1994).

Buffer Width and Effectiveness in Protecting Wetland Habitat and Providing Habitat in Adjacent Uplands

This section summarizes the literature that identified ranges of widths of uplands that protect wetland habitat and/or that provide adjacent upland habitat for wildlife species that use wetlands. The literature presents findings in a variety of ways. Some studies identify the distance that target species range from a wetland source, while other researchers identified the distances that species travel between wetlands. Synthesis documents outlined recommendations for buffer widths based on a review of research findings. Some of the literature identified use of habitats by broad categories of wildlife guilds, while other studies focused on limited guilds or even individual species.

It is important to understand that the range of buffer widths identified and discussed in the literature is a reflection of many variables including the objectives of the research, the species/guilds studied and their varied life-history needs, and the methods of the research. Thus, it is not appropriate to choose a single study or buffer dimension to justify a buffer dimension, whether large or small. It is critical to incorporate the life-history requirements of the range of targeted species when considering buffer dimensions. Synthesis documents clarify that a range of upland habitat buffer dimensions may be appropriate depending upon site considerations, landscape context, and targeted species.

For example, in summarizing the literature he reviewed on buffer effectiveness, McMillan (2000) concluded, "An appropriate buffer to maintain wildlife habitat functions for all but the most highly degraded wetlands would be comprised of native tree and/or shrub vegetation and range from 30 to 100 meters [98 to 328 feet]." Other authors have reached similar conclusions, with their buffer recommendations varying depending on the type of wildlife, life-history stage, intensity of adjacent land use, and surrounding landscape (Groffman et al. 1991a, Castelle et al. 1992b, Desbonnet et al. 1994, Semlitsch 1998). Because there is often substantial information on the needs for some specific wildlife groups, the research findings that are relevant for birds, amphibians, reptiles, and mammals are provided below. Following this discussion, Table 5-5 provides a summary of literature on general habitat needs in relation to buffer sizes.

One consideration not found for this synthesis was the implication of the condition of the upland buffer relative to its provision of wildlife habitat. In several studies on the use of upland buffers by native species, the study identified that the buffer was upland forest. However, no studies were reviewed for this synthesis that compared wildlife use of mature forested buffers with buffers composed of meadow, shrubland, harvest forest, or younger forests. Some research has identified the importance of intact forest habitat to wetland-related species (Azous and Horner 2001, Richter 1997), but a comparison study was not found for this synthesis.

Generally, wildlife-species have varying needs for different types of adjacent habitat for different life needs, such as breeding, foraging, and resting (Brown 1985). This makes it difficult to prescribe one particular type of habitat as best for wildlife. Habitat is very species specific. However, as a general rule, most researchers have recommended that buffers be maintained or restored to a forested condition if only for the screening function they provide. (Obviously, this has little relevance to the shrub-steppe ecoregion in Eastern Washington, where trees are rarely found.)

Birds

The research on birds ranges from studies in individual species to summaries on bird species richness. A tremendous amount of research on waterfowl exists, with the majority being conducted in the prairie pothole region of the United States. This section focuses on studies or syntheses that are relevant to the Pacific Northwest.

The Puget Sound Stormwater Management Research Program found that a distance of 1,640 feet (500 m) from a wetland edge was necessary to account for total species richness of birds (Richter and Azous 2001b). In a study of bird use of freshwater wetlands in urban King County, Washington, Milligan (1985) determined that bird species diversity was strongly correlated with the percentage of the wetland boundary that was buffered by at least 49 feet (15 m) of trees and shrubs.

In eastern Washington, Foster et al. (1984) determined that 68% of waterfowl nests were in upland areas within 98 feet (30 m) of the wetland edge, whereas it would take a 312-foot (95 m) buffer to encompass 95% of the nesting sites.

Temple and Cary (1988) created a computer model whose results may relate to the breeding success of forest birds using wetland buffers. Estimating the effects of habitat fragmentation on birds breeding in the interior of forests in Wisconsin, their model predicted that nesting success was strongly correlated to distance to the edge of a forest. The computer model predicted a success rate of 70% for nests greater than 656 feet (200 m) from the forest edge, 58% for a distance of 328 to 656 feet (100 to 200 m), and only 18% for nests less than 328 feet (100 m) from the forest edge. Applying these findings to wetland buffers, those less than 100 feet (30 m) in width might not be expected to support bird species that nest in forest interiors. The authors concluded that, without "recruits" (birds moving into appropriate habitat niches from farther afield), the continued fragmentation of forest habitats could lead to local extinction of populations of birds that use the interior of forests.

Amphibians

The research on amphibians and buffers in relation to their habitat needs comes both from studies in the Pacific Northwest and literature summaries from around the United States. Findings are rather consistent in that amphibians range substantial distances from breeding locations in a wetland to fulfill their life-history needs. On the west side of the Cascades, there appears to be a preference for forested habitats adjacent to breeding sites. Urban land uses near breeding sites seem to have a negative influence on amphibian abundance.

Detailed findings include:

- A study in the Puget Sound lowlands documented a decline in amphibian richness in wetlands where forest in the contributing watershed was diminishing. Results were not linked to buffer dimensions (Richter and Azous 2001a).

- In a study in King County by Ostergaard (2000), the greatest use of stormwater ponds by native breeding amphibians was found when 3,280 feet (1,000 m) of forested habitat was available adjacent to the pond.

- A study of pond-breeding salamanders in the eastern U.S. found that a buffer of 534 feet (164 m) would be needed to encompass 95% of adult and juvenile salamanders. This buffer range may apply to other similarly mobile species (Semlitsch 1998). Buffers of 98 to 328 feet (30 to 100 m) were recommended along riparian zones, depending upon slope, stream width, and adjacent use (Semlitsch 1998).

- Salamanders use upland habitats over 1,969 feet (600 m) from the edge of wetlands for non-breeding life-history stages. Sustaining viable amphibian species closely associated with wetlands requires maintaining the connection between wetlands and terrestrial habitats (Semlitsch 1998).

See Table 5-5 for further information on these studies.

In addition, in the Midwestern U.S., Knutson et al. (1999) found a positive correlation between the presence of forest around the perimeter of the wetland and amphibian abundance, and a negative correlation to urban land uses on the perimeter.

Reptiles

Western pond turtles are associated with a variety of aquatic habitats, including wetlands, streams, and rivers. In a California study, western pond turtles were found to overwinter as far as 1,650 feet (500m) from water (Reese and Welsh 1997). An unpublished study done in Washington for the Washington Department of Wildlife found nest sites as far as 615 feet (187m) from water, usually in open areas with good sun exposure (Holland 1991).

Research on freshwater turtles in North Carolina found that turtles used a wide area for nesting and terrestrial hibernation in uplands surrounding the ponds where breeding occurred (Burke and Gibbons 1995). They found that a 902-foot (275 m) buffer was required to protect 100% of the nest and hibernation sites. Protecting 90% of the sites required a 240-foot (73 m) buffer. The authors concluded that most buffer requirements are inadequate to protect turtle habitat for all stages of their life-history.

Mammals

Use of wetlands by mammals depends upon adjacent uplands. The literature indicates that even a mammal that is closely associated with wetlands, such as a beaver, uses upland habitats an average of 100 feet (30 m) from the wetland edge in eastern Washington and over 300 feet (100 m) distant in western Washington (Castelle et al. 1992b). Research on small mammals found the greatest concentration of species near riparian corridors, with some species found within that riparian corridor that were not found farther away in upland habitats (Cross 1985).

Dimensions of effective buffers for mammals are more difficult to discern from the literature because they depend upon the species' life-history. Also, as discussed in Section 4.11 of Chapter 4, habitat linkages and fragmentation may be more critical for the sustainability of some populations.

As part of the Puget Sound Stormwater Management Research Program, Richter and Azous (2001c) found that the highest richness of small mammals was in wetlands with at least 60% of the first 1,640 feet (500 m) of buffer in forest cover. Other findings of this program include:

- The preservation of large woody debris within the wetland and adjacent upland forest is important for maintaining small-mammal habitat.
- Small-mammal richness was best associated with the combined factors of wetland size, adjacent forest, and the quantity of large, coarse woody debris within the wetland and its buffer.

- In southwestern Oregon, Cross (1985) conducted research on small mammals in "leave-strips" adjacent to streams within zones of forest that had been harvested. He found that the richness of small-mammal species was highest in the riparian zone closest to the stream, intermediate in the transition zone, and lowest in the upland zone. (The zones were defined by vegetation composition, not by dimension.) Because riparian habitats provide more niches for species, it is expected that such habitats would maintain greater species richness (Cross 1985).

Cross also found no species in the upland zone that were not found in the riparian zone, but he found five species present in the riparian zone that were not present in the upland or transition zones. A strip averaging 220 feet (67 m) wide supports mammal communities at similar numbers and richness to the nearby undisturbed riparian corridor. This study focused on small mammals which, relative to large mammals, have small home ranges. Therefore, the study is not broadly applicable to appropriate leave-strip dimensions for larger species.

Table 5-5 presents a summary of literature on wildlife and buffer/upland habitat use that was relevant to this synthesis. As noted previously, some of the research is specific to individual species, some is focused on a particular guild or group of similar species, some looks at life-history patterns (nesting distances), and some sources represent synthesis documents of buffer effectiveness. These distances do not necessarily reflect the literature relative to human disturbance and/or habitat fragmentation, which are discussed in the next sections.

It is difficult to synthesize the findings of the research on wildlife and the width of buffers into simple generalizations that can be readily applied. When looking at life-history needs (e.g., nesting sites, foraging ranges, etc.), the distances presented in the literature range from 98 feet (30 m) (Foster et al. 1984, Castelle et al. 1992b) to 3,280 feet (1,000 m) (Richter 1997). These distances, measured in the field, represent the distance that species ranged, nested, or foraged from a wetland edge.

Other authors have presented their own synthesis or recommendations of effective buffer ranges based on review of the literature. These range from 49 feet (15 m) (Desbonnet et al. 1994) to 328 feet (100 m) (Groffman et al. 1991a, Castelle et al. 1992b, Desbonnet et al. 1994, McMillan 2000). Note that Desbonnet et al. (1994) recommends a range of buffer dimensions based on site conditions, species of interest, and proposed adjacent land uses; hence, their studies are cited at both ends of the distance spectrum.

Table 5-5. Summary of studies on wildlife habitat provided by buffers.

Author(s)	Date	Width	Comments
Allen	1982	328 – 590 feet (100 – 180 m)	Mink use: generally concentrated within 330 feet (100 m) of water but will use upland habitats up to 590 feet (180 m) distant
Burke and Gibbons	1995	240 feet (73 m): 90% 902 feet (275 m): 100%	Buffer to encompass % nesting and hibernation of turtles in North Carolina

Author(s)	Date	Width	Comments
Castelle et al.	1992b	197 – 295 feet (60 – 90 m): Western Washington 98 – 197 feet (30 – 60 m): Eastern Washington	Range for all species they noted Range for all species they noted
Castelle et al.	1992b	263 feet (80 m) avg. - 590 feet (180 m)	Wood duck nesting locations from wetland edge (non-Washington data)
Castelle et al.	1992b	98 feet (30 m): Eastern Washington 328 feet (100 m): Western Washington	Distance of beaver use of upland habitats from water edge
Chase et al.	1995	98 feet (30 m) or more	100 feet (30 m) would be "adequate"; buffers larger than 100 feet needed to meet habitat needs, including breeding for birds and some mammals
Cross	1985	220 feet (67 m)	Forested "leave-strips" for small mammal richness adjacent to streams in SW Oregon
Desbonnet et al.	1994	49 – 98 feet (15 – 30 m): low intensity 98 – 328 feet (30 – 100 m): high intensity	Variable buffer widths using adjacent land uses as decision-making criteria
Fischer et al.	2000	98 feet (30 m) minimum	Literature review; majority of literature cited recommends buffer widths of 330 feet (100 m) for reptiles, amphibians, birds, and mammals
Foster et al.	1984	98 feet (30 m): 68% of nests) 312 feet (95 m): 95% of nests	Waterfowl breeding use of wetlands in the Columbia Basin greatest in smaller (<1 acre [0.4 ha]) wetlands; 68% of waterfowl nests within 100 feet (30 m) of wetland edge; to encompass 95% of waterfowl nests would require 310 feet (95 m) of buffer
Groffman et al.	1991a	197 - 328 feet (60 - 100 m)	For most wildlife needs
Groffman et al.	1991a	328 feet (100 m)	Neotropical migratory bird species
Howard and Allen	1989	197 feet (60 m)	For most wildlife needs
McMillan	2000	98 – 328 feet (30 – 100 m)	Based on a synthesis of literature
Milligan	1985	49 feet (15 m)	Bird species diversity strongly correlated with the percentage of the wetland boundary buffered by at least 50 feet (15 m) of tree and shrub vegetation
Norman	1996	164 feet (50 m)	To protect wetland functions; more buffer may be required for "sensitive wildlife species"

Author(s)	Date	Width	Comments
Ostergaard	2001	3,280 feet (1,000 m)	Forested habitat surrounding stormwater ponds, related to native amphibian richness
Richter	1996	3,280 feet (1,000 m)	Literature review and synthesis
Richter	1996	3,280 feet (1,000 m)	Native amphibian use
Richter and Azous	2001b	1,680 feet (512 m)	Distance from wetland edge necessary to include all bird richness in Puget Sound lowland wetlands
Richter and Azous	2001c	1,640 feet (500 m): 60%	Highest small-mammal richness when 60% of first 1,640 feet (500 m) of buffer was forest habitat
Semlitsch	1998	1,969 feet (600 m)	Salamanders
Semlitsch	1998	228 – 411 feet (69.6 - 125.3 m) 539 feet (164.3 m) for 95% of all species	Six species of adult salamanders and two species of juveniles; mean distance from wetland edge was 228 feet (juveniles) – 411 feet (adults). To incorporate 95% of all species, buffer mean would have to be 539 feet
Short and Cooper	1985	164 – 328 feet (50 – 100 m)	164 feet (50 m) for foraging
Temple and Cary	1988	> 656 feet (200 m): 70% success 328 – 656 feet (100 – 200 m): 58% success < 328 feet (100 m): 18% success	Nesting success rates for interior-dwelling forest birds related to distance into the interior of a forest from the forest edge

5.5.4.2 Screening Adjacent Disturbances

Wetland buffers screen wildlife from human activities. Disturbance from humans can come in the form of noise and light (indirect effects) or from human presence/movement (direct effects). Noise and light can disrupt feeding, breeding, and sleeping habits of wildlife. Many wildlife species in wetlands are disturbed by unscreened human activity within 200 feet (61 m) (Washington Department of Wildlife in Castelle et al. 1992b). Dense shrubs and trees in a wetland buffer can limit intrusion and screen out noise, light, and movement from adjacent human development (Castelle et al. 1992b).

In addition, domestic pets such as dogs and cats can adversely affect wetland wildlife by preying on some wildlife species and are particularly damaging to ground-nesting species (Churcher 1989). See Section 4.12.5 in Chapter 4 for further discussion.

The effect of noise on wildlife is a topic of growing concern. Little research exists on the effective buffer widths required to filter sounds for wildlife. See Section 4.12.3 in Chapter 4 for a discussion of current literature on the effects of noise on wildlife.

Groffman et al. (1991a) determined that 105 feet (32 m) of dense, forested buffer was necessary to reduce noise from commercial areas to background noise levels. Shisler et al. (1987) differentiated between the impacts of low-intensity land uses (agricultural, recreational, low-density housing) and high-intensity land uses (high-density residential, commercial/industrial). They found that low-intensity land uses could be effectively screened with vegetated buffers of 49 to 98 feet (15 to 30 m), while high-intensity land uses required buffers of 98 to 164 feet (30 to 50 m).

Direct sighting of humans approaching was found to disrupt birds (i.e., change their behavior or cause flushing) between 46 and 164 feet (14 to 50 m) (Shisler et al. 1987, Josselyn et al. 1989, Rodgers and Smith 1997). Looking specifically at great blue herons, Short and Cooper (1985) documented that they would flush from their nests if humans approached within 328 feet (100 m). Buffers between 46 and 164 feet (14 to 50 m) may be required to screen wildlife from direct observation of humans, while larger buffers (328 feet or 100 m) were documented as necessary to screen nesting herons.

Other researchers differentiated between the types of activities humans are engaged in and their effects on wildlife. Humans walking toward birds were studied to see how closely they could approach before birds flushed from perches or stopped foraging. In Florida, Rodgers and Smith (1997) found that humans could approach 46 to 112 feet (14 to 34 m) before flushing, but automobiles flushed birds at 61 to 78 feet (18.5 to 24 m). Interestingly, they found that bird-watching (as opposed to humans who were simply walking) had the greatest adverse impacts on birds. They surmised this was due to the human behavior of stopping and standing with binoculars at one point for a prolonged time.

Cooke (in Castelle et al. 1992b) analyzed 21 wetland sites in western Washington and concluded that buffers smaller than 50 feet (15 m) were generally ineffective in screening human disturbance from alterations such as noise, debris, and altered use of the buffer.

Table 5-6 summarizes the findings of the literature related to the disturbance limits or screening effects of a buffer for various wildlife species.

Table 5-6. Summary of studies on screening provided by buffers.

Author(s)	Date	Width	Comments
Castelle et al.	1992b	200 feet (61 m)	General wildlife considerations
Cooke	1992	50 feet (15 m)	Analyzed 21 sites in King County. Buffers less than 50 feet were often disturbed by human activities and were not effective at screening "human effects." Found in Castelle et al. (1992b)
Groffman et al.	1991a	105 feet (32 m)	Dense forest to filter sound from commercial land uses to natural background levels
Josselyn et al.	1989	49 – 164 feet (15 – 50 m)	Unscreened human activity within 50 – 164 feet was disruptive to waterbirds in San Francisco Bay area

Author(s)	Date	Width	Comments
Rodgers and Smith	1997	46 to 112 feet (14 –34 m) 61 to 78 feet (18.5 – 24 m)	Waterbirds in Florida: flushing distance from walkers 46 – 112 feet; flushing distance from autos 61 – 78 feet. Nature observation had greatest impact if involving walking activities. Nesting birds tolerated closer human approach than birds that were perching/foraging
Shisler et al.	1987	50 - 100 feet (15 – 30 m) 100 – 164 feet (30 – 50 m)	Low-intensity land uses (agriculture, recreation, and low density residential): 50 - 100 feet High-density residential housing and commercial/industrial: 100 - 164 feet Most effective buffers had steep slopes, dense shrubs
Short and Cooper	1985	328 feet (100 m)	328 feet to buffer nesting great blue herons from human disturbance

5.5.4.3 Maintaining Habitat Connections

Converting habitats to other uses directly increases the isolation of wetlands and the fragmentation of habitats (See Section 4.11 in Chapter 4 for further discussion of the impacts of fragmentation). Buffers can play a role in reducing habitat fragmentation by serving as upland habitat directly adjacent to a wetland. They can also provide an area that can connect, or be part of a corridor that connects, wetlands with upland habitats or other water bodies (National Research Council 2001). However, buffers, as applied in a regulatory context, are rarely designed to provide these connections. Typical buffer widths generally are insufficient to link wetlands to other habitats. In addition, maintaining linkages from one habitat type to another on individual parcels is often not a consideration when properties are reviewed case by case. The authors of Volume I believe that maintaining habitat connectivity is best accomplished through landscape-scale planning and protection measures.

In general, the literature states that for terrestrial species with wide-ranging habits, it is important to maintain connections between sites used for breeding, feeding, and refuge. This is critical for maintaining population viability (Bedford and Preston 1988, Gibbs 1993, Semlitsch and Bodie 1998, National Research Council 2001). One may assume that this applies only to large terrestrial mammals. However, research has shown that many native amphibians on the west side of the Cascades can range 3,280 feet (1,000 m) from source wetlands into other wetlands or surrounding upland habitats (Richter 1997). Ostergaard (2001) found the greatest amphibian richness in sites that had upland forest habitat surrounding the site by 3,280 feet (1,000 m). Richter and Azous (2001b) found that a radius of 1,680 feet (512 m) surrounding a wetland was necessary to include all the bird richness of species utilizing the source wetland.

5.5.4.4 Summary of Key Points

- There is no simple, general answer for what constitutes an effective buffer width for wildlife considerations. The width of the buffer is dependent upon the species in question and its life-history needs, whether the goal is to maintain connectivity of habitats across a landscape, or whether one is simply trying to screen wildlife from human interactions.

- The majority of wildlife species in Washington use wetland habitats for some portion of their life-history needs. Many species that are closely associated with wetlands (those that depend upon wetlands for breeding, brood-raising, or feeding) depend upon surrounding upland habitats as well for some life-history stages.

- Many terrestrial species that are dependent upon wetlands have broad-ranging habits, some over 3,280 feet (1,000 m) from the source wetland. Although this might be expected for large mammals such as deer or black bears, it is also true for smaller species, such as salamanders and other amphibians.

- Human access and land uses adjacent to wetlands influence the use and habits of wildlife through noise and light intrusions, as well as elimination or degradation of appropriate upland habitats. Even "passive" activities, such as bird/nature-watching, have been shown to have effects on roosting and foraging birds.

- Synthesis documents that evaluated many studies discussing the protection of habitat provided by wetland buffers generally recommend buffer widths between 50 and 300 feet (15 to 100 m), depending on specific factors. These factors include the quality of the wetland habitat, the species needing protection, the quality of the buffer, and the surrounding land uses.

5.5.5 Buffer Maintenance and Effectiveness over Time

Buffers can help to protect wetlands for as long as the buffers themselves remain intact. Buffer areas can be altered over time by human disturbance and natural events, such as windstorms. In addition, some researchers have raised the issue of whether buffers have a long-term, carrying capacity with regard to filtration and binding of pollutants. In other words, is there a maximum amount that can be processed before the buffer's ability is overwhelmed?

5.5.5.1 Human Alteration to Buffers

Human activities are the most common mechanism for altering buffers over time. Buffer functions can be reduced if vegetation is cut or trampled, soils are compacted, sediment loading surpasses the filtering capability of the vegetation, or surface-water flows create channels and subsequent erosion.

Cooke (in Castelle et al. 1992b) analyzed 21 wetland sites in western Washington and concluded that buffers less than 50 feet (15 m) wide were more susceptible to being reduced over time by human disturbance. Nearly all of the buffers they studied that were less than 50 feet (15 m) in width were significantly reduced in the few years the buffers had been present on the back of private lots. Some of the buffers were found to have been eliminated through complete clearing of native vegetation. Of the buffers wider than 50 feet (15 m), most still had some portion intact and, overall, showed fewer signs of human disturbance. Cooke also found that fencing buffers (without a gate allowing access) was effective at reducing the alteration of buffers by humans.

In a study in the Monterey Bay area of California, Dyste (1995) examined 15 wetlands with buffers. All of the buffers suffered from human alteration including cutting of vegetation, soil compaction, and dumping of garbage.

5.5.5.2 Loss of Trees to Blowdown

In the Pacific Northwest, forested buffers are often leave-strips around wetlands or along streams when the surrounding forest is cleared for land development. These forested strips are then exposed to winter windstorms, which are common, often resulting in substantial loss of large trees due to blowdown.

Pollock and Kennard (1998) concluded that trees in narrow forested buffers (less than 76 feet [23 m] wide) have a much higher probability of suffering significant mortality from windthrow and blowdown than trees in wider buffers. They conclude that buffers in the range of 76 to 115 feet (23 to 35 m), created when the surrounding forest is cut, are the minimum width that can be expected to withstand the effects of wind in the long term.

5.5.5.3 Reduced Capacity for Sediment/Nutrient Removal

Many of the studies described earlier assessed the effectiveness of buffers in removing sediments and nutrients for short durations (on the order of one to two years, if the time period was discernable in the methods sections of the literature). One study that assessed water quality improvement over longer periods found that effectiveness diminished as the outer margins of the buffers became saturated with sediment (Dillaha and Inamdar 1997). Their findings suggest that buffers have a limited carrying capacity for sediment removal (a maximum amount of sediment that can be removed) and that larger buffers and other methods may be required to ensure long-term control of sediment.

Similarly, Todd (2000) cites work by Dillaha in 1993 that found less than 10% of grass filter strips were effective after three to five years. The grass filter strips became channelized and surface flows were no longer passing through as sheet flow that would allow contact with vegetation to remove sediments and nutrients. Todd emphasizes that, for buffers to be effective, they have to be sustainable over time, and this must be a factor when determining buffer widths.

5.5.5.4 Summary of Key Points

- Human actions can reduce the effectiveness of buffers in the long term through removal of buffer vegetation, soil compaction, sediment loading, and dumping of garbage.
- Buffers may lose their effectiveness to disperse surface flows over time as flows create rills and channels, causing erosion within the buffer.
- Leaving narrow strips of trees can result in tree loss due to blowdown.
- Buffers may become saturated with sediment over time and become less effective at removing pollutants. The literature indicates that this should be considered when determining buffer widths.

5.5.6 Summary of Buffer Ranges and Characteristics from the Literature

The following discussion summarizes the many suggestions and recommendations in the literature for how buffer widths can be established. Many of these were found in synthesis documents that summarize scientific literature on buffers and then draw general conclusions. The recommendations in most of these syntheses are remarkably consistent. Taken together with the great number of site-specific studies cited in the syntheses, they present what should be considered "fundamental principles" for buffers.

At its most basic level, the science on wetland buffers identifies four criteria that should be considered in determining the width of a buffer (Castelle et al. 1992b, Desbonnet et al. 1994, Norman 1996, McMillan 2000, Todd 2000):

- The functions and values of the aquatic resource to be protected by the buffer
- The characteristics of the buffer itself and of the watershed contributing to the aquatic resource
- The intensity of the adjacent land use (or proposed land use) and the expected impacts that result from that land use
- The specific functions that the buffer is supposed to provide; for habitat functions this includes the targeted species to be managed and an understanding of its habitat requirements

The feasibility or possibility of incorporating those four considerations into determining buffer dimensions is dependent upon the jurisdiction in question. Ideally, buffer widths should be tailored to these four factors. However, the authors that recommend considering these factors also acknowledge that the scientific basis for determining the width of a buffer is often superseded by political expediency. Buffers are more often

determined administratively as standard or fixed dimensions that may, or may not, be correlated with the criteria listed above.

Table 5-7 presents a summary of the buffer ranges recommended by the authors who conducted literature reviews or syntheses on buffer effectiveness. Minimums ranged from 25 feet (8 m) to 197 feet (60 m). Maximums ranged from 98 feet (30 m) for some land uses to 350 feet (107 m).

Table 5-7. Summary of recommendations for buffer dimensions from the literature.

Author(s)	Date	Minimum Buffer	Maximum Buffer	Comments
Castelle et al.	1994	50 to 100 feet (15 - 30m)		"Minimum buffers necessary to protect wetlands and streams under most circumstances"
Fischer et al.	2000	98 feet (30 m)	328 feet (100 m)	Larger buffer for reptiles, amphibians, birds and mammals
Groffman et al.	1991a	197 feet (60 m)	328 feet (100 m)	For most wildlife needs
Howard and Allen	1989	197 feet (60 m)		For most wildlife needs
McMillan	2000	25 feet (8 m)	350 feet (107 m)	Case by case, using a rating system and the intensity of proposed or existing land use for protecting most wetland functions
Norman	1996	164 feet (50 m)		To protect wetland functions; more may be required to protect more "sensitive wildlife species"

Table 5-8 is taken from one of the most comprehensive buffer syntheses published (Desbonnet et al. 1994). The authors of the synthesis looked at several hundred articles and reports on buffers. This table presents the information in a format that outlines the general effectiveness of different buffer widths at removing pollutants and providing habitat.

Table 5-8. A summary of the effectiveness of pollutant removal and the value of the wildlife habitat of vegetated buffers according to buffer width (Desbonnet et al. 1994).

Buffer Width in Feet (Meters)	Pollutant Removal Effectiveness	Wildlife Habitat Value
16 feet (5 m)	Approximately 50% or greater sediment and pollutant removal	Poor habitat value; useful for temporary activities of wildlife
32 feet (10 m)	Approximately 60% or greater sediment and pollutant removal	Minimally protects stream habitat; poor habitat value; useful for temporary activities of wildlife
49 feet (15 m)	Greater than 60% sediment and pollutant removal	Minimal general wildlife and avian habitat value
66 feet (20 m)	Greater than 70% sediment and pollutant removal	Minimal wildlife habitat value; some value as avian habitat
98 feet (30 m)	Approximately 70% or greater sediment and pollutant removal	May have use as a wildlife travel corridor as well as general avian habitat
164 feet (50 m)	Approximately 75% or greater sediment and pollutant removal	Minimal general wildlife habitat value
246 feet (75 m)	Approximately 80% or greater sediment and pollutant removal	Fair to good general wildlife and avian habitat value
328 feet (100 m)	Approximately 80% or greater sediment and pollutant removal	Good general wildlife habitat value; may protect significant wildlife habitat
656 feet (200 m)	Approximately 90% or greater sediment and pollutant removal	Excellent general wildlife value; likely to support a diverse community
1,968 feet (600 m)	Approximately 99% or greater sediment and pollutant removal	Excellent general wildlife value; supports a diverse community; protection of significant species

Castelle et al. (1994), summarizing research conducted primarily before 1990, concluded "buffers necessary to protect wetlands and streams should be a minimum of 49 to 98 feet (15 to 30 m) in width under most circumstances." They note that the lower end of the spectrum is the minimum necessary to maintain physical and chemical processes, while the upper end of the spectrum may be the minimum necessary to maintain biological processes. The Castelle et al. report of 1994 does not identify appropriate maximums. McMillan (2000) recommends an approach to determining buffers that attempts to balance predictability with flexibility by setting standard buffer widths that can be altered on a case-by-case basis to adapt to site-specific factors. This approach for determining buffer width incorporates a rating system for wetlands, plus an assessment of the intensity of proposed or existing adjacent land use, to establish buffer widths ranging from 25 to 350 feet (8 to 107 m). It is perhaps the method that is closest to fitting the four bulleted criteria outlined at the beginning of this section. It incorporates an understanding of the condition of the wetland, the buffer, and the proposed adjacent land use.

Several other authors also suggest that considering site-specific factors enhances the effectiveness of buffer strips over using fixed-width buffers (Steinblums et al. 1984,

Norman 1996, Todd 2000). Belt and O'Laughlin (1994) note that, "The fixed minimum-width approach enjoys the virtue of simplicity in application, but has the potential for providing either not enough or too much protection."

Liquori (2000) also cautions against using fixed buffer widths to protect long-term ecological functioning of buffers and their associated aquatic resources. He notes that many of the functions that buffers provide are directly related to physical characteristics and biological processes within the buffers. Informed with site-specific information, a case-by-case argument could be made for establishing buffer widths. "The nature of the [functions a buffer provides] may significantly depend upon riparian structure both locally and as a mosaic over the watershed scale."

In urban settings, larger buffer widths are often prescribed in anticipation of future impacts from adjacent land use and activity upstream in the watershed. The most important criterion for determining buffer width is identification of the various functions the buffer is expected to provide (Todd 2000).

In agricultural lands, Welsch (1991) identifies a three-zone approach for establishing buffers:

- **Zone 1** consists of riparian-type trees and shrubs immediately adjacent to the stream, water body, or wetland. It should be a minimum 13 feet (4 m) wide, or adjusted to include the entire riparian area (the area with year-long or seasonal soil-moisture regime influenced by the stream or water body). Minimum length should be the length of the proposed disturbance outside the riparian management zones, or "the longest distance possible."

- **Zone 2** extends upslope from Zone 1 and consists of vegetation that may be periodically harvested as it matures. A minimum distance of 20 feet (6 m) should be allowed for this zone for small streams or water bodies; for larger streams or water bodies the total of Zones 1 and 2 can be increased up to 98 feet (30 m) or 30% of the geomorphic floodplain (whichever is less). Minimum length should match that of Zone 1. Zone 2 can be an active harvest zone, but trees and vegetation need to be left to provide soil holding and filtering capacity.

- **Zone 3** is added upslope of Zone 2 if adjacent land (away from the aquatic resource) is cultivated cropland or another land use with the potential for erosion or sediment production. Zone 3 is a vegetated filter strip and should be wide enough to control "concentrated flow erosion from cultivated cropland." Zone 3 vegetation should be established prior to the establishment of Zones 1 and 2.

This zonal approach is recommended for active agricultural activities, which implies the regular creation of conditions with high erosion potential (grazing or tilling). It also allows more active use of the central portion of the buffer and active management of the outer area of the buffer.

Townsend and Robinson (2001) build on this zonal approach and recommend guidance on maintenance of canopy coverage and closure. They suggest using species that readily

resprout from stumps or roots in the areas nearest the stream channels (to allow the vegetation to respond to flood damage and/or beaver activity). They stress the need for ongoing maintenance, especially in Zone 3, to ensure that erosive flows are not causing rills or channelized flows into Zone 2. They also note that, while most of these buffers will be applied on an ownership basis, greater benefit would be realized if the concept of zoned buffers were applied on a watershed basis.

Other recommendations are based on wildlife species of particular interest. Based on their study of waterbirds in Florida, Rodgers and Smith (1997) recommend a buffer width of 328 feet (100 m) to ensure that birds will not be triggered into an "approach" response, a state which occurs prior to actual flushing. They derived this figure by analyzing the flushing distance from human approach for 16 species, then adding 131 feet (40 m) to that distance. The 131-foot (40 m) distance was derived from previous work which found that birds became alert (stopped their ongoing behavior and focused on the approaching human) in a range of 82 to 131 feet (25 to 40 m).

5.5.6.1 Summary of Key Points

- Many researchers have recommended using four basic criteria to determine the width of a buffer:
  - the functions and values of the aquatic resource to be protected by the buffer
  - the characteristics of the buffer itself and of the watershed contributing to the aquatic resource
  - the intensity of the adjacent land use (or proposed land use) and the expected impacts that result from that land use
  - the specific functions that the buffer is supposed to provide including the targeted species to be managed and an understanding of their habitat needs
- Protecting wildlife habitat functions of wetlands generally requires larger buffers than protecting water quality functions of wetlands
- Effective buffer widths should be based on the above factors. They generally should range from:

  25 to 75 feet (8 to 23 m) for wetlands with minimal habitat functions and low-intensity land uses adjacent to the wetland

  75 to 150 feet (15 to 46 m) for wetlands with moderate habitat functions and moderate or high-intensity land uses adjacent to the wetland

  150 to 300+ feet (46 to 92+ m) for wetlands with high habitat functions, regardless of the intensity of the land uses adjacent to the wetland
- Fixed-width buffers may not adequately address the issues of habitat fragmentation and population dynamics. Several researchers have recommended

a more flexible approach that allows buffer widths to be varied depending on site-specific conditions.

5.6 Chapter Summary and Conclusions

Wetlands are defined using well established language that is generally consistent between federal and state laws. However, certain wetland types are sometimes excluded from regulation. These include small wetlands, isolated wetlands, and wetlands that are designated as Prior Converted Croplands (PCC). The scientific literature makes clear that small wetlands and isolated wetlands provide important functions and does not provide any rationale for excluding these wetlands from regulation. Little scientific information is available on PCC, but there is no evidence to suggest that they are unimportant in providing wetland functions. They retain many of the characteristics necessary to provide multiple wetland functions.

Wetland delineation is conducted according to either the federal or state delineation manual. These manuals are consistent and, when applied correctly, will result in the same wetland boundary. Wetland rating systems are a useful tool for grouping wetlands based on their needs for protection. The most widely used method in Washington is the state's rating system which places wetlands in categories based on their rarity, sensitivity, irreplaceability, and functions.

Wetland buffers are a critical tool for protecting wetland functions. Findings regarding buffer functions and effectiveness are consistent in recommending that the width of a buffer should be related to the wetland functions that need protection, the land-use activities from which the wetland is being buffered, and the characteristics of the buffer itself. These factors, derived from the many studies of wetland buffers and other aquatic resources, can be thought of as the "fundamental principles" that are recommended to determine the widths and characteristics of buffers.

The literature confirms that for water quality improvement (e.g., sediment removal and nutrient uptake) there is a non-linear relationship between buffer width and increased effectiveness. Sediment removal and nutrient uptake are provided at the greatest rates within the immediate outer portions of a buffer (nearest the source of sediment/nutrient), with increasingly larger widths of buffers required to obtain measurable increases in those functions. Additionally, the long-term effectiveness of buffers in providing such mechanical and biological processes is not well documented in the literature. However, the literature suggests that buffers may have a carrying capacity or limit to their ability to remove pollutants. Future research on this topic is needed.

Compared to the widths needed for sediment removal and nutrient uptake, the literature has documented the need for significantly wider buffers to protect or maintain habitat functions for wildlife species that are closely associated with wetlands, as well as for populations that use wetlands. Research confirms that many wildlife species and guilds are dependent upon wetlands for only portions of their life cycles, and that they require upland habitats adjacent to the wetland to meet all their life needs. Without adequate

upland habitat adjacent to wetlands, these habitat functions are lost. Some species use upland habitats that are far from the source wetland. The literature documents that, without access to appropriate upland habitat and the opportunity to move between wetlands and other habitats across a landscape, it is not possible to maintain viable populations of many species. Beyond simply providing adequate upland habitat adjacent to a single wetland, the literature on the maintenance of wildlife populations finds that it is necessary to link habitat types, including wetlands and uplands, across a landscape in order to maintain genetically viable populations.

Several authors who suggested recommendations for buffer widths based on their own synthesis of the literature have recommended variable widths based on the conditions of the wetland, the conditions of the buffer, the proposed land uses adjacent to the buffer, and what functions are intended to be managed. For protection and maintenance of wildlife habitat functions of wetlands, these studies suggest that effective buffer widths should be based on the above factors and generally should range from: 25 to 75 feet (8 to 23 m) for wetlands with minimal habitat functions and low-intensity land uses adjacent to wetlands; 50 to 150 feet (15 to 46 m) for wetlands with moderate habitat functions and moderate or high-intensity land use that is adjacent; and 150 to 300+ feet (46 to 92+ m) for wetlands with high habitat functions depending on the intensity of the adjacent land use. However, several authors noted that protection and maintenance of viable wildlife populations for many species requires habitat connections via corridors and large habitat patches.

Chapter 6 continues the discussion of regulatory tools used to manage wetlands by discussing wetland compensatory mitigation and its effectiveness.

Chapter 6

The Science and Effectiveness of Wetland Mitigation

6.1 Reader's Guide to this Chapter

This chapter synthesizes the scientific literature regarding compensatory mitigation and its effectiveness at reducing the severity of activities that detrimentally affect wetlands. It also reports the suggestions made by various authors regarding ways to improve compensatory mitigation.

6.1.1 Chapter Contents

Major sections of this chapter and the topics they cover include:

Section 6.2, Introduction and Background to Wetland Mitigation describes wetland mitigation sequencing, which encompasses a series of actions that requires addressing each action, or step, in a particular order. Compensation for wetland impacts is just one of these steps.

Section 6.3, Success of Compensatory Mitigation Wetlands synthesizes the literature on the biological, ecological, or functional success of compensatory mitigation projects. This section does not specifically evaluate the successful compensation for wetland area; that is discussed in Section 6.7.

Section 6.4, Compliance with Permit Requirements describes studies that evaluated several aspects of how well compensatory mitigation projects met legal or permit requirements. These included whether projects were completed or installed according to plan, whether they attained the required wetland acreage, whether performance standards were achieved, whether the project was monitored or maintained, and whether the regulatory agencies followed-up on the project.

Section 6.5, Types of Compensatory Mitigation discusses the use and effectiveness of restoration, creation, enhancement/exchange, preservation, mixed compensatory mitigation, mitigation banking, and in-lieu fees.

Section 6.6, Replacement Ratios describes the rationale for the use of ratios in determining the acreage required as compensation for a given area of wetland impact. It synthesizes the literature on the ratios that were required and those actually achieved for numerous projects. This section also discusses approaches proposed in the literature to more effectively determine compensatory mitigation ratios.

Section 6.7, Replacement of Wetland Acreage summarizes the results of studies examining whether compensatory wetland mitigation is actually replacing the acreage of wetland losses authorized. This includes both evaluations of overall permitting programs and of specific compensation projects in compensating for wetland acreage.

Section 6.8, Functions and Characteristics Provided by Created, Restored, or Enhanced Wetlands describes the ability of mitigation wetlands to provide wildlife habitat, plant communities, adequate soil conditions, and water quality/quantity functions. Compensation wetlands were often compared with pre-existing or reference wetlands in these studies.

Section 6.9, Reproducibility of Particular Wetland Types summarizes the literature regarding whether and how easily certain wetland types, such as bogs, fens, vernal pools, alkali wetlands, and mature forested wetlands, can be reproduced or restored.

Section 6.10, Suggestions from the Literature for Improving Compensatory Mitigation summarizes numerous recommendations made by researchers to improve the success of compensation projects—ranging from improvements to regulations and site selection, to better performance standards, to a broader landscape approach, to mitigation banking.

Section 6.11, Chapter Summary and Conclusions ties together the major concepts presented in the chapter.

6.1.2 Where to Find Summary Information and Conclusions

Each major section of this chapter concludes with a brief summary of the key points resulting from the literature review on that topic in a bullet list format. The reader is encouraged to remember that a review of the entire section preceding the summary is necessary for an in-depth understanding of the topic.

For summaries of the information presented in this chapter, see the following sections:

- Section 6.3.2
- Section 6.4.9
- Section 6.5.8
- Section 6.6.4
- Section 6.7.3
- Section 6.8.6
- Section 6.9.5
- Section 6.10.7

In addition, Section 6.11 provides a summary of the chapter and conclusions about the overarching themes gleaned from the literature and presented in this chapter.

6.1.3 Sources and Gaps in Information

The synthesis in this chapter is based on more than 50 articles, government reports, and conference proceedings that have been published since about 1990 on the topic of compensatory mitigation. (The literature did not address the other types of mitigation listed in Section 6.2.1.)

The information resulted from studies conducted in various states and countries, including several studies from the Pacific Northwest. Environmental conditions may vary in other states and countries. However, the information resulting from these studies is relevant to compensatory wetland mitigation in Washington State for the following reasons:

- The general principals and techniques used to restore, create, and enhance wetlands are similar
- The regulatory approaches and requirements are similar
- Most importantly, the studies provide similar and consistent results

Geographic location of the studies cited in this chapter

The articles and reports that evaluated the effectiveness of individual compensatory mitigation projects focused on a variety of locations, including Washington, Oregon, California, Louisiana, Michigan, Indiana, Ohio, New Jersey, Massachusetts, Maryland, Tennessee, and Florida.

Studies that assessed specific functions performed by wetlands that were sites for compensatory mitigation and non-regulatory restoration were located in: Washington, Oregon, Wyoming, Iowa, Minnesota, Wisconsin, Illinois, Ohio, New York, Pennsylvania, Connecticut, West Virginia, South Carolina, Florida, Canada, Sweden, Spain, Austria, and central Europe.

The information synthesized in this chapter covers a range of topics and issues relating to compensatory wetland mitigation (refer to Chapter Contents, Section 6.1.1). Yet there are some topics and issues for which no scientific information was found. For example, studies were found that examined whether compensation projects had performance standards and whether the performance standards were met. However, no studies were found that explored why performance standards were not met. Other examples of data gaps include studies that:

- Determined the effectiveness of local critical area ordinances at replacing permitted wetland losses
- Examined the effect of construction inspections, monitoring, maintenance, or performance bonding on the success or level of compliance of projects
- Compared the level of success of newly installed versus more established compensation sites

- Looked specifically at the quality and effectiveness of preservation sites
- Focused specifically on wildlife habitat provided by restored, created, or enhanced wetlands in urban settings
- Examined the effects of mitigation decisions on a watershed scale
- Looked at the reproducibility of alkali wetlands

The articles and reports reviewed used a variety of terms to define what they were assessing or evaluating. For the purposes of this synthesis, *effectiveness* is used as a general term referring to how compensatory wetland mitigation was doing overall, including evaluations of success, compliance, and functions and characteristics. These terms will be defined more precisely in subsequent sections.

6.2 Introduction and Background to Wetland Mitigation

6.2.1 Wetland Mitigation Sequence

Mitigation is a series of actions that requires addressing each action, or step, in a particular order. This sequence of steps is used to reduce the severity of negative impacts from activities that potentially affect wetlands. When a change in land use has the potential to adversely affect a wetland, regulatory agencies require the applicant to illustrate how the project has considered the six sequential steps of mitigation. According to the rules implementing the Washington State Environmental Policy Act (Chapter 197.11 WAC), mitigation involves the following:

1. *Avoiding the impact altogether by not taking a certain action or parts of an action;*

2. *Minimizing impacts by limiting the degree or magnitude of the action and its implementation, by using appropriate technology, or by taking affirmative steps to avoid or reduce impacts;*

3. *Rectifying the impact by repairing, rehabilitating, or restoring the affected environment;*

4. *Reducing or eliminating the impact over time by preservation and maintenance operations during the life of the action;*

5. *Compensating for the impact by replacing, enhancing, or providing substitute resources or environments; and/or*

6. *Monitoring the impact and taking appropriate corrective measures* (WAC 197.11.768).

The authors of Volume 1 provide a brief explanation and examples of the steps in the mitigation sequence in the following paragraphs.

Avoidance is the first step in the mitigation sequence. Avoidance of impacts means that there is no direct loss of wetland area and functions. Avoidance does not, however, eliminate indirect losses of wetland function. For example, consider a hypothetical proposal to develop a 5-acre parcel of land. The parcel contains 2 acres of wetland. The development is designed around the wetland and will therefore avoid any direct loss. Avoidance has occurred. Yet if buildings and parking lots surround the wetland, indirect impacts to wildlife habitat and hydrology may occur in the form of fragmentation and altered hydroperiod.

Minimization of adverse impacts is the second step. It can reduce the extent of wetland impacts when a project is redesigned to lessen wetland alteration. However, it does not eliminate the direct or indirect loss of area and/or functions.

Rectification, the third step, assumes that losses in wetland area and/or function at the impact site are temporary and can be restored. For example, projects such as installing or maintaining an underground pipeline that passes through a wetland typically use rectification as a mitigation measure. In the example of the underground pipeline, vegetation, soil, and water movement may be disturbed and altered. The wetland area and/or functions are temporarily changed or lost. Rectification would entail replacing the soil, restoring the water movement, and restoring the vegetation.

The fourth step of the mitigation sequence is not generally relevant to wetlands, and therefore, no examples of its application are provided.

Compensation for unavoidable adverse impacts, the fifth step, involves restoring, creating, enhancing, or preserving wetland area to replace or make-up for the wetland area and functions that were lost or altered. It is discussed in much greater detail in the following sections.

Monitoring, step 6, is used to address the potential impact to wetlands that may result from a project when specific impacts are not known. If impacts are observed during or after project completion, actions should be taken to address the loss of wetland functions. For example, if a bridge is built over a river fringed by wetlands, the bridge may shade portions of the wetlands. Though no wetlands would be filled during construction, the shading could alter the performance of functions, thereby resulting in impacts to wetlands. To address the potential risk of impacts to wetlands, the project could be monitored to determine the effect of shading on the riverine wetlands. If monitoring reveals that the functions of the riverine wetlands were adversely altered, then compensation might be required.

The scientific literature reviewed for this synthesis did not contain information on the use or effectiveness of any of the mitigation measures defined above, except compensatory mitigation, which is the focus of the remainder of this chapter.

6.2.2 The Emergence of Compensatory Wetland Mitigation

The term *compensatory mitigation* refers to the compensation stage of the mitigation sequence (number 5 in the list of steps described earlier). Compensatory wetland mitigation generally entails performing one or more of the following types of compensation:

- Restoring wetland conditions (and functions) to an area
- Creating new wetland area and functions
- Enhancing functions at an existing wetland
- Preserving an existing high-quality wetland to protect it from future development

The term **compensatory mitigation** refers to the compensation stage of the mitigation sequence (number 5 in the list of steps on the previous page). Because the regulatory requirements and policies tend to focus on the compensation stage, the term "mitigation" is often used to refer to compensation, which is just one part of the overall mitigation sequence.

The use of compensatory mitigation for wetland loss emerged in the 1980s (Roberts 1993, National Research Council 2001). The U.S. Army Corps of Engineers considered the process of mitigation as part of the National Environmental Policy Act of 1969. However, it wasn't until 1980 when the U.S. Environmental Protection Agency (EPA) issued new guidelines for Section 404(b)(1) of the Clean Water Act that mitigating for wetland losses by creating or restoring another wetland as compensation became widely acceptable (National Research Council 2001). Compensatory mitigation was seen as a way to speed up an arduous process of documenting avoidance and minimization efforts, while satisfying concerns about the loss of ecosystems and functions (Roberts 1993). Creating or restoring wetland area to compensate for permitted wetland losses was viewed and publicized as a way to allow development while preventing a net loss of wetland areas.

By the late 1980s, studies of the effectiveness of compensatory mitigation were emerging, with mixed results. The primary indication was that replacing or replicating an existing wetland was difficult, if not impossible (Kusler and Kentula 1990, National Research Council 2001). However, some wetland types and functions could be approximated given the proper conditions (Kusler and Kentula 1990, National Research Council 2001). This chapter focuses on studies published since 1990 that examined the effectiveness of compensatory mitigation.

6.3 Success of Compensatory Mitigation Wetlands

Compensatory mitigation "success" is poorly defined and often contentious (Kentula 2000). The literature refers to legal success, biological success, ecosystem success (Wilson and Mitsch 1996), functional success (Mockler et al. 1998), or some combination of these.

Compliance generally means the same as "legal success." It is evaluated by comparing the actual on-the-ground, or as-built, conditions against what was required in the permit. Studies describing legal success are referred to as compliance in this document, and they are discussed in Section 6.4.

This section will focus on "biological, ecological, or functional success." Therefore, when the term *success* is used in this chapter, it refers exclusively to biological, ecological, or functional success. Success involves an evaluation of the factors that characterize a wetland (e.g., hydroperiod, vegetation, soils), the performance of functions, or both. Best professional judgment and/or one of a variety of function assessment methods have been used by researchers to evaluate success.

The authors of Volume 1 have observed two main problems with evaluating the success of compensatory mitigation projects. First, success is often confused with compliance, and it is assumed that they must go hand in hand. In some cases, compliance and success may be separate considerations. For example, a compensation site may be in compliance with its permit requirements and not be considered a success because it does not replace the functions of the wetland that was lost. On the other hand, a site may fall short of meeting its permit requirements, perhaps because performance standards were unrealistic. The site is therefore not in compliance, yet it may still be determined a success because it compensates for the wetland functions lost.

The second problem involves time; when should a project be evaluated for success? For example, two years after installation a compensation site may not be meeting its performance standards, perhaps because the site has too much bare ground, percent aerial cover of native vegetation is too low, or cover by invasive plant species is too high. The site is, therefore, neither in compliance nor a success. However, looking at the same site five or six years after installation, the site may have experienced rapid growth of native shrubs and trees, native volunteer species may have colonized the bare ground, and maintenance activities may have controlled invasive plants. At this time, the site could be evaluated as a success and considered to be in compliance.

Rather than judging the success or failure of a compensatory wetland mitigation project at a single point in time, Zedler and Callaway (2000) proposed evaluating how a project progresses over time. The authors suggest that a focus on progress would encourage proponents to acknowledge problems occurring at a site and look for solutions. Zedler (2000) proposes that more compensation projects should be viewed as experiments without a specific desired outcome. In lieu of attaining a specific level of performance, projects would be monitored as experiments for at least 25 years. The regulatory framework currently in place, however, does not support this method of evaluation due to the relatively short timeframe allowed for monitoring and assessing the compliance of compensation projects (Breaux and Serefiddin 1999, Zedler 2000).

Refer to Section 6.10.4 for more information on performance standards. Specifically, Section 6.10.4.1 discusses shortcomings of existing performance standards, and Section 6.10.4.3 discusses the need for longer monitoring periods.

6.3.1 Results of Literature Studies

Several studies determined the level of success of compensatory mitigation projects (Table 6-1). Though the data indicated that some projects were successful and some projects were unsuccessful, most compensation projects had an intermediate level of success, meaning they were neither fully successful nor completely unsuccessful.

- 25 to 66% of projects were determined to have an intermediate level of success
- 3 to 43% of projects achieved full success
- 7 to 97% of projects were unsuccessful, though half of the studies found that at least 20% of projects were unsuccessful (Johnson et al. 2002, Michigan Department of Environmental Quality 2000, Mockler et al. 1998, Sudol and Ambrose 2002)

The methods used to evaluate the success of compensatory wetland mitigation projects varied from best professional judgment (Storm and Stellini 1994) to function assessments (Wilson and Mitsch 1996, Balzano et al. 2002), to quantitative measures of vegetation cover and survival (Allen and Feddema 1996), or some combination (Michigan Department of Environmental Quality 2000, Johnson et al. 2002). Though the methods of evaluation differed, most studies considered similar variables such as wetland area, hydrologic conditions, wildlife suitability, vegetation, and soils.

Table 6-1. Results of studies examining the success of compensatory mitigation.

Location of Study	No. of Projects Evaluated	Level of Success	Evaluation Criteria
Washington State (Johnson et al. 2002)	24	13% fully successful 33% moderately successful 33% minimally successful 21% not successful	Wetland acreage, performance standards, goals/objectives, contribution to functions, comparison with wetland lost
Washington/ King County (Mockler et al. 1998)	38	3% successful 97% not successful	Replacing the functions of the wetland lost. Examined vegetation survival and areal coverage, hydrology, soil, wetland and buffer condition assessment, wildlife habitat, and invasive species
Western Washington (Storm and Stellini 1994)	17	23% functioned well ecologically 65% functioned poorly 12% were not completed	Vegetation diversity, non-native plant dominance, structural diversity, wildlife use, adjacent land uses, vegetation cover vs. open water

Location of Study	No. of Projects Evaluated	Level of Success	Evaluation Criteria
Southern California (Allen and Feddema 1996)	75	32 successful 9 mostly successful 10 half successful 5 unsuccessful 8 under construction 5 not initiated 6 did not require mitigation	Project installed according to plan; percent cover of vegetation (dead, living, and invasive)
California/ Orange County (Sudol and Ambrose 2002)	55	16% successful 58% partially successful 26% failures	Qualitative evaluation based on habitat quality (e.g., vegetation density and diversity, invasive species, tree height)
Ohio (Wilson and Mitsch 1996)	5	1 high 2 medium to high 1 medium 1 medium to low	WETII evaluation (Adamus et al. 1989) - hydrology, soils, vegetation, wildlife, water quality
New Jersey (Balzano et al. 2002)	74	Wetland Mitigation Quality Assessment scores were indexed from 0 (low) to 1 (high). The average score was 0.51, and the range was 0.25 to 0.83	Hydrology, soils, vegetation, wildlife suitability, site characteristics, and landscape features
Michigan (Michigan Department of Environmental Quality 2000)	69	22% successful overall 78% unsuccessful overall	Project's legal rating (permit compliance) and biological rating (wetland acreage). Does not include enhancement

6.3.2 Summary of Key Points

- Success is defined as meeting biological or ecological criteria, which may include an assessment of functions.
- The majority of compensatory wetland mitigation projects were found to be neither fully successful nor completely unsuccessful, meaning that most projects had an intermediate level of success, relative to biological or ecological functions.
- Though the methods used to evaluate project success differed, the studies considered similar criteria, such as vegetation, soils, and hydrologic conditions.

6.4 Compliance with Permit Requirements

Regulatory agencies typically require wetland compensation for authorized, unavoidable wetland impacts. A wetland mitigation plan is reviewed and approved as part of the permit approval process. It outlines how wetland impacts will be compensated for. The mitigation plan identifies how the project will be designed. It addresses wetland acreage, hydroperiod, vegetation, goals, objectives, performance standards, monitoring, maintenance, contingency actions, and long-term protection. These are the parameters by which regulators often measure compliance.

According to the Merriam-Webster dictionary, compliance means "conformity in fulfilling official requirements." Regarding compensatory wetland mitigation, compliance means that a project has satisfied or is satisfying the legal requirements and obligations identified in a permit.

Most studies that examined compliance investigated how well a compensatory wetland mitigation project complied overall (i.e., with all applicable permit requirements). Several of these studies only reported the results of the overall evaluations. Other studies evaluated how well projects complied with individual requirements, such as:

- Installation – whether the project was installed
- Installation according to plan – whether the project was constructed according to the approved mitigation plan and design
- Wetland area establishment – whether the project obtained the acreage of wetland that was required
- Performance standards/goals/objectives attainment – whether the project performed as anticipated
- Monitoring – whether the project was monitored as required (or was required to be monitored)
- Maintenance – whether project maintenance was performed (or required)

Studies also reviewed regulatory follow-up - whether any regulatory agencies made an attempt to track an individual project after the permit was issued.

Each of these types of evaluations is discussed in subsequent sections.

6.4.1 Compliance Overall

Several studies attempted to determine how well a project complied with several or all of its permit requirements. Because permit requirements vary by state and over time, not all compliance evaluations considered the same criteria or requirements. Where specified, the requirements evaluated by a given study are identified in Table 6-2.

Twelve studies evaluated overall compliance with regulatory requirements for compensatory wetland mitigation projects (Table 6-2). In Washington State four studies that evaluated compliance were conducted in the past decade (Storm and Stellini 1994, Mockler et al. 1998, Johnson et al. 2000, Johnson et al. 2002), and two studies were conducted in Oregon (Gwin and Kentula 1990, Shaich and Franklin 1995).

The studies in Washington found that 29% of compensation projects complied with their regulatory requirements. In Oregon, studies revealed that compliance of projects ranged from zero to 36%.

Studies from other states demonstrated more variability in levels of compliance. Results ranged from less than 20% to about 80% of projects in compliance (Holland and Bossert 1994, De Weese 1998, Morgan and Roberts 1999, Michigan Department of Environmental Quality 2000, Brown and Veneman 2001, Balzano et al. 2002, Sudol and Ambrose 2002).

More recent studies (published in 2000 or after) did not report higher levels of compliance than studies conducted in the 1990s. One might therefore assume that compensation projects have not improved over the years. However, it is important to realize that as knowledge of wetland science and compensatory mitigation has improved and evolved, permit requirements have likewise evolved (Kentula 2000). More recent studies may have been evaluating compensation projects that were being held to a higher standard than projects permitted and evaluated in the 1990s (Sudol and Ambrose 2002). However, a study by Cole and Shafer (2002) in Pennsylvania observed that permit requirements had not changed noticeably over the 14-year range of permits they evaluated (1986-1999).

Table 6-2. Level of overall compliance of compensation projects.

Location of Study	No. of Projects Evaluated	% of Projects in Compliance with all Requirements	Evaluation Criteria
Washington (Johnson et al. 2000)	45	29%	• Project installed • Installed according to plan • Meet performance standards
Washington (Johnson et al. 2002)	24	29%	• Establish required wetland acreage • Meet performance standards • Meet goals/objectives
Washington/western (Storm and Stellini 1994) [a]	17	18%	• Installation of both development and compensatory mitigation projects as required

Location of Study	No. of Projects Evaluated	% of Projects in Compliance with all Requirements	Evaluation Criteria
Washington/King County (Mockler et al. 1998)[b]	29 (38)	21% (16%)	• Meet performance standards - vegetation survival, areal cover, invasive species • Design - hydrology, slopes • Installation - soil • Maintenance - mowing, weeding
Oregon/Portland metro area (Shaich and Franklin 1995) [c]	72	36%	• Project installed • Upland buffer area/vegetation requirements • Requirements for timing of project construction • Wetland vegetation requirements • Hydrology requirements • Requirements for water control structures • Fencing requirements
Oregon/Portland metro area (Gwin and Kentula 1990)	11	0%	• Construction plans match permit specs • As-built matches permit specs: wetland area/shape • Actual slopes match planned slopes • Vegetation established as planned
California/ Orange County (Sudol and Ambrose 2002) [d]	57	53%	• Project installed • Meet performance standards/ permit conditions
California/ vernal pools (De Weese 1998)	25	83%	• Attaining performance standards required by Corps
Massachusetts (Brown and Veneman 2001) [e]	109 (7)	43% (100%)	• Project installed • Compensation project of required size • Water inputs sufficient for wetland conditions • At least 75% cover wetland plants (FAC or wetter)
Tennessee (Morgan and Roberts 1999)	50	12%	• Establish required acreage of wetland • Meet performance standards

Location of Study	No. of Projects Evaluated	% of Projects in Compliance with all Requirements	Evaluation Criteria
Michigan (Michigan Department of Environmental Quality 2000) [f]	74	18%	• Mitigation acreage requirement • Implementation of approved mitigation plan • Conservation easement • Submittal of as-built plans • Monitoring • Placement of elevated wildlife structures • Construction schedule with specified completion date • Prohibited actions • Corrective measures identified • Financial assurances
Louisiana (Holland and Bossert 1994)	9	78%	• Meet Corps of Engineers permit conditions
New Jersey (Balzano et al. 2002)[g]	88	48% weighted average	• Grading (56% concurrence) • Hydrology (47% concurrence) • Soil (51% concurrence) • Vegetation cover (39% concurrence) • Vegetation survival (28% concurrence) • Design (56% concurrence)

[a] Compliance not determined for 53% of projects due to lack of information.

[b] 38 projects examined; 9 not completed. Compliance information for 38 projects is in parentheses.

[c] Not all projects had requirements for all criteria (e.g., only 8% had a requirement for fencing).

[d] Calculated from data provided.

[e] 5 projects did not result in wetland impact and were subtracted from the project total. Results were recalculated from the data provided. Parentheses = data for variance projects (received more oversight).

[f] Permit conditions from the criteria list were considered if specified in permit.

[g] Evaluated concurrence with applicable criteria. Percent = average concurrence score for 88 projects. Average concurrence score for each criterion provided in parentheses.

6.4.2 Project Installation

A number of studies investigated whether mitigation projects had even been constructed or installed. In these studies, mitigation projects were either randomly selected from a database or a complete inventory of all projects permitted during a specific timeframe was conducted. Four studies were conducted in Washington. Studies in seven other states, including Oregon, also investigated whether mitigation projects had been installed.

Results indicated that most projects were installed (Table 6-3). The four studies from Washington found that 74 to 93% of compensatory mitigation projects had been installed. Studies from most of the other states showed similar results (64 to 99%). However, studies performed in Florida and Tennessee revealed that less than half of the compensatory wetland mitigation projects had been installed (Erwin 1991, Morgan and Roberts 1999).

Due to the relatively high percentage of projects that were installed, one could assume that the low levels of overall compliance result from inadequate design, installation, maintenance, follow-up, or some combination.

Table 6-3. Percent of compensatory mitigation projects that were installed.

Location of Study	No. of Projects Evaluated	Percent of Projects Installed
Washington (Johnson et al. 2000)	45	93%
Washington/ King County (Mockler et al. 1998)	38	76%
Washington/ western (Storm and Stellini 1994)	17	88%[a]
Washington (Kunz et al. 1988)	35	74%
Oregon/ Portland metro area (Shaich and Franklin 1995)	90	99%
California/ southern (Allen and Feddema 1996)	75	93%
California/ Orange County (Sudol and Ambrose 2002)	57	96%[a]
Michigan (Michigan Department of Environmental Quality 2000)	159	85%
Indiana (Robb 2002)	333	64%
Massachusetts (Brown and Veneman 2001)[b]	109	77%
Tennessee (Morgan and Roberts 1999)	100	47%
Florida (Erwin 1991)	NA	~40% [c]

[a] Calculated from data provided.

[b] Five projects did not result in wetland impact and were subtracted from the project total. Results were recalculated from the data provided.

[c] "Out of more than 100 permitted projects requiring wetland mitigation only 40 had undertaken any mitigation activity."

6.4.3 Installation According to Plan

Another aspect of determining mitigation compliance is evaluating whether a mitigation project has been installed according to its approved plan. When compensatory wetland mitigation is necessary to offset proposed wetland losses, regulatory staff generally

require a wetland mitigation plan. The mitigation plan should provide specific information about project construction, including detailed design drawings. Approval of a permit for wetland loss is often contingent upon approval or acceptance of the wetland mitigation plan.

It is commonly assumed that a project will be built exactly as it is designed. However, many factors during construction and installation can influence what is actually built on the ground. Therefore, permit requirements often require (or recommend) submittal of an as-built plan or report that documents the final installed conditions of a site after construction is complete. When available, as-built drawings are used to document the baseline conditions for monitoring of a site.

Three studies evaluated whether compensation projects were installed according to approved plans (Table 6-4). Results from both Washington and New Jersey indicate that more than half of the compensatory mitigation projects were installed according to requirements (Johnson et al. 2000, Balzano et al. 2002). Johnson et al. (2000) found that 55% of the projects were installed to plan. For those that submitted an as-built plan or report, 88% of the projects were installed according to plan. A study in Oregon, however, determined that none of the projects were implemented according to plan (Gwin and Kentula 1990). All three studies mentioned grading and vegetation as the elements of the plan that were not implemented according to the approved plan.

It can be hypothesized that the divergent results noted in the studies above might be the result of an increase of knowledge and expertise over time. For instance, the projects reviewed by Gwin and Kentula (1990) were designed, permitted, and constructed in the early 1980s. Since that time much has been learned by those who design, construct, and regulate compensatory mitigation projects. It is possible that improved designs, experience and skill in implementing the designs, and improved regulatory follow-up have resulted in a higher percentage of projects being installed according to plan by the mid- to late 1990s. The current scientific literature does not address this possibility.

Table 6-4. Percent of compensatory mitigation projects installed according to plan.

Location of Study and Reference No.	No. of Projects Evaluated	Percent Installed to Plan	Aspects Not Installed to Plan
Washington (Johnson et al. 2000)	42	55%	Mainly vegetation, also grading, misc. plan elements (e.g., fences, signs)
Oregon/ Portland metro area (Gwin and Kentula 1990)	11	0%	Size, shape, slopes, and vegetation
New Jersey (Balzano et al. 2002)	88	56%	Incorrect elevations, sizes, and/or shapes

6.4.4 Establishment of Wetland Acreage

Compensatory wetland mitigation projects are intended to compensate for the loss of wetland area and functions. Hence, permits and mitigation plans often identify a specific acreage of compensation required to offset those losses. Establishing the required acreage is therefore an important criterion of regulatory compliance. (Functions provided by compensatory mitigation projects are discussed in Section 6.8.)

Thirteen studies examined compensatory wetland mitigation sites to determine if the acreage of wetlands required by the permits had been established (Table 6-5). The studies presented the data from these investigations in two ways.

- **The percentage of projects establishing the required wetland acreage.** Researchers determined if each project met its required wetland acreage, then reported how many projects actually met the wetland acreage requirement as a percentage of the total number of projects considered. A few studies mentioned a specific threshold, such that a project had to be smaller than required by a specific acreage or percentage in order to fail to meet its wetland area (Brown and Veneman 2001, Johnson et al. 2002, Morgan and Roberts 2003).
- **The percentage of compensatory wetland acreage established.** Researchers determined the total acreage of compensatory mitigation that was verified as wetland for all the projects considered. The study then reported the total acreage of wetland compensation that was established as a percentage of the total acreage that was required for all the projects considered.

Over half of projects achieved the required wetland area in Washington and Oregon (Shaich and Franklin 1995, Johnson et al. 2002). In fact, the majority of studies determined that about half of the compensation projects established the required acreage of wetland. However, three studies found that less than 30% of projects met their acreage requirements (McKinstry and Anderson 1994, Balzano et al. 2002, Morgan and Roberts 2003). In New Jersey only 7% of projects achieved the wetland acreage requirements (Balzano et al. 2002).

For the total acreage of wetland achieved versus required, a study from Washington determined that 84% of the required acreage of compensatory wetlands was established (Johnson et al. 2002), while a study in Oregon found about 70% of the required wetland acreage was established (Gwin and Kentula 1990). Results from other states indicated between 44 and 74% of the required wetland acreage had been established.

Why is there a discrepancy between the percent of projects achieving acreage and the percentage of total acreage established? New Jersey, for example, found that only 7% of compensation projects achieved the required wetland acreage, yet 63% of the total required wetland acreage was established. It can be hypothesized that this is due to small, individual projects that establish a portion of the required acreage but fall short of the total amount required. For example, a site that was required to provide 1 acre of mitigation but only provided 0.8 acre would not meet the acreage criteria. However, the 0.2-acre difference may represent a very small fraction of the total acreage of compensation evaluated for a large study, thereby affecting the total acreage percentage very little.

Table 6-5. Establishment of required wetland acreage.

Location of Study	No. of Projects Evaluated	% of Projects Achieving Required Wetland Area	% of Required Wetland Area that Was Established
Washington (Johnson et al. 2002)[a]	24	58%	84%
Oregon/Portland metro area (Shaich and Franklin 1995)[b]	72	53% [e]	NA
Oregon/Portland metro area (Gwin and Kentula 1990)	11	NA	71%
California/southern (Allen and Feddema 1996)[c]	75	NA	69%
California/Orange County (Sudol and Ambrose 2002)	55	52%	NA
Wyoming (McKinstry and Anderson 1994)	64	14% [e]	NA
New Jersey (Balzano et al. 2002)	85	7%	63%
Tennessee (Morgan and Roberts 1999)	50	28%	68%
Ohio (Wilson and Mitsch 1996)	5	40%	66%
Indiana (Robb 2002)	31	NA	44%
Michigan (Michigan Department of Environmental Quality 2000)	159	50%	NA
Massachusetts (Brown and Veneman 2001)[d]	109	46%	NA
Florida (Erwin 1991)	NA	NA	74%

NA= information not available

[a] West of the Cascades, projects established 92% of the required acreage; east side projects established 25% of the required acreage.

[b] Compensation wetlands were 16 acres (6.5 ha) short of the 69 acres required.

[c] Projects > 8.5 acres (3.4 ha) resulted in a net gain of 17 acres (6.9 ha) of wetland area, while projects < 8.5 acres resulted in a net loss of almost 25 acres (10 ha).

[d] Five projects did not result in wetland impact and were subtracted from the project total. Results were recalculated from the data provided.

[e] Calculated from data provided.

6.4.5 Attainment of Goals, Objectives, and Performance Standards

Another critical component of compliance for a compensatory wetland mitigation project is determining whether the project has met its goals, objectives, and/or performance standards. Goals, objectives, and performance standards are generally included as part of an approved wetland mitigation plan. Goals and objectives are intended to provide a blueprint for what the project proposes to accomplish in terms of anticipated wetland type, specific habitat, functions, and/or values. The performance standards are intended to provide measurable criteria to determine if the project has accomplished its goals and objectives (Hruby et al. 1994, Ossinger 1999).

Two separate factors were investigated in the studies reviewed:

- Whether a project had goals, objectives, and performance standards
- Whether projects were meeting their goals, objectives, and performance standards

Data in Table 6-6 indicate that at least three-quarters of projects had goals, objectives, or both (Erwin 1991, Storm and Stellini 1994, Johnson et al. 2002). However, fewer projects met the goals/objectives (10 to 38%) according to the two studies that reported this information (Erwin 1991, Johnson et al. 2002).

In general, performance standards were specified less frequently than goals and objectives, though at least half of the projects had them (Erwin 1991, Storm and Stellini 1994, Mockler et al. 1998, Johnson et al. 2000, Cole and Shafer 2002). Two studies conducted in Washington determined that 21% of projects met their performance standards (Mockler et al. 1998, Johnson et al. 2002), while a third study from Washington found that 35% of projects met performance standards (Johnson et al. 2000).

A review of the articles suggests that the percent of projects with performance standards increased with more recent projects. For example, Storm and Stellini (1994) and Cole and Shafer (2002) evaluated compensation projects that were permitted in the mid to late 1980s or early 1990s. Performance standards may not have been as rigorously required (Cole and Shafer 2002) or they may not have been specifically identified as performance standards. For example, of 10 projects that did not contain performance standards, 30% were permitted in the late 1980s and 80% were permitted prior to 1995, while 20% were permitted in the late 1990s (Cole and Shafer 2002).

Data suggest (Table 6-6) that the more recent projects did not appear any more likely to meet performance standards than earlier projects (Mockler et al. 1998, Johnson et al. 2000, Cole and Shafer 2002, Johnson et al. 2002). Some believe that performance standards have become more rigorous overtime, and more recent projects have been held to a higher standard. Cole and Shafer (2002), however, did not find that performance standards noticeably changed in terms of content from projects permitted in the late 1980s to the late 1990s. Therefore, one can conclude that the year of permitting does not appear to be a factor in whether projects met their performance standards.

More information on performance standards is provided in Section 6.10.4.

Table 6-6. Attainment of goals, objectives, and performance standards.

Location of Study	No. of Projects Evaluated	% of Projects w/ Goals or Objectives	% of Projects w/ Performance Standards	% of Projects Meeting Goals or Objectives	% of Projects Meeting Performance Standards
Washington (Johnson et al. 2000)	34	NA	87%[a]	NA	35%
Washington (Johnson et al. 2002)	24	92%	NA	38%	21%

6.4.6 Monitoring

To determine if a compensatory wetland mitigation project is in compliance, it is necessary to monitor the project over time. Monitoring requirements are typically identified in the wetland mitigation plan. The duration, frequency, and methods of monitoring should depend on the goals, objectives, and performance standards for the project.

Monitoring is the process through which data about site conditions is gathered. Monitoring data is used to determine whether a project is achieving its performance standards, and therefore its goals and objectives, within a predicted timeframe. Monitoring also provides critical information about whether a site requires maintenance or contingency actions. Monitoring is therefore essential for a project to achieve compliance.

The studies investigating whether compensatory wetland mitigation projects were required to be monitored and whether monitoring actually occurred are summarized in Table 6-7. In general, studies conducted more recently found that monitoring was required for a greater percentage of projects. Data from four studies indicate monitoring

was required for at least three-fourths of projects (Erwin 1991, Morgan and Roberts 1999, Johnson et al. 2000, Michigan Department of Environmental Quality 2000). The remaining two studies, which examined compensation projects permitted in the late 1980s and early 1990s, found that monitoring was required for a third to half of projects (Holland and Kentula 1992, Storm and Stellini 1994).

Less than half of the projects had monitoring data. However, the studies did not determine whether the monitoring was not conducted or whether there was simply no record of the monitoring reports on file with the regulatory agencies. Since over half of the studies mentioned difficulty finding complete project information from the agency files (Storm and Stellini 1994, Morgan and Roberts 1999, Johnson et al. 2000, Cole and Shaffer 2002), it is possible to conclude that monitoring reports may have been submitted to the appropriate agencies but the reports were lost due to a lack of follow-up and poor file maintenance. If monitoring is not conducted there is no means to trigger maintenance or contingency actions. The consequence of inadequate follow-up by regulatory agencies is discussed in Section 6.4.8.

Table 6-7. Percent of projects requiring monitoring and those actually monitored.

Location of Study	% of Projects Requiring Monitoring	% of Projects Monitored
Washington (Johnson et al. 2000)	71%	33%
Washington/ western (Storm and Stellini 1994)	53%	18%
California (Holland and Kentula 1992)	32%	NA
Michigan (Michigan Department of Environmental Quality 2000)	87%	35%
Pennsylvania (Cole and Shafer 2002)	NA	<10%
Tennessee (Morgan and Roberts 1999)	89%	43%
Florida (Erwin 1991)	98%	38%[a] (62%)[b]

[a] Represents projects that were adequately monitored.

[b] Calculated from Erwin (1991) indicating all projects that received some level of monitoring.

6.4.7 Maintenance

Compensatory wetland mitigation sites require maintenance to help ensure that goals and performance standards will be achieved. Maintenance includes implementing corrective actions to rectify problems, such as an insufficient water supply or inappropriate water regime, invasive species infestation (e.g., reed canarygrass, bull frogs), trash, vandalism, or anything else that may result in non-compliance with permit requirements. Johnson et al. (2002) observed that a lack of maintenance was one of the main reasons for poor success of mitigation projects.

Results revealed that permitting agencies did not require all compensation projects to provide maintenance. Studies discovered that permits required site maintenance for 41 to 78% of projects (Erwin 1991, Storm and Stellini 1994, Michigan Department of Environmental Quality 2000). However, even fewer projects (20 to 60%) complied with their maintenance requirements (Erwin 1991, Michigan Department of Environmental Quality 2000).

The research did not investigate the reasons for low compliance with maintenance provisions. One may assume that it is linked to inadequate monitoring, lack of regulatory follow-up, or a lack of cooperation from the owner of the site.

6.4.8 Regulatory Follow-Up

Once compensatory wetland mitigation is required, it is the responsibility of the regulatory agencies to track the project over time and determine if it complies with permit requirements. A regulatory agency follows up on compensatory mitigation projects by:

- Ensuring that the compensation project is constructed as designed and approved, or that the applicant documents, through "as-built" reports why approved plans were modified during installation
- Ensuring that required monitoring reports are submitted on schedule
- Performing site visits to confirm monitoring results and attainment of performance standards
- Ensuring maintenance actions are undertaken on schedule
- Ensuring that appropriate contingency measures are enacted
- Ensuring the compensation site is protected over the long-term (i.e. through a legal protection mechanism such as a conservation easement)

Studies in Washington and Oregon indicated that about half of compensatory wetland mitigation projects received some regulatory follow-up in the form of site visits, phone calls, or letters (Kentula et al. 1992, Johnson et al. 2002). In Michigan only about a quarter of projects received any kind of follow-up after the permit was issued (Michigan Department of Environmental Quality 2000).

A few studies also examined the effect of regulatory follow-up on project compliance, success, or both. Robb (2002) alluded to the fact that the high number of non-compliant compensation projects resulted from a lack of follow-up and enforcement actions. In Washington a study noted that all of the projects lacking regulatory follow-up were either minimally or not successful, while two-thirds of the projects receiving some kind of follow-up were either fully or moderately successful (Johnson et al. 2002).

One team of researchers observed:

> *The most ecologically successful sites were generally those that had received follow-up work in the form of maintenance, replanting, or improvements to grading or water control structures in accordance with recommendations made by NJDEP [New Jersey Department of Environmental Protection] and other regulatory agencies after initial compliance inspections revealed problems* (Balzano et al. 2002).

Studies indicated that regulatory follow-up can help to ensure the success of compensation sites (Johnson et al. 2002, Balzano et al. 2002). It is assumed that applicants will be more likely to abide by permit requirements and submit monitoring reports if regulatory agencies are actively following up on projects. Since monitoring reports are meant to identify what is working and where there are shortfalls, maintenance actions can be initiated or contingency measures can be triggered to correct the shortfalls and problems as soon as possible. Therefore, one can conclude that agency follow-up improves the compliance and success of compensation projects.

6.4.9 Summary of Key Points

- Most compensatory wetland mitigation projects were installed. However, compliance levels overall were generally low.
- Two out of three studies found that more than half of projects were installed according to plan. Projects not installed to plan most often did not comply with grading and vegetation requirements.
- The majority of studies found that about 50% of projects achieved their required wetland acreage.
- Even if individual projects did not fully achieve their required acreage, most studies found that at least 66% of the overall required acreage of compensation had been established.

- The requirement for monitoring as a regulatory condition seems to be increasing in more recent studies (30 to 50% in the early 1980s; 75% in more recent studies).
- Over 50% of the studies noted that it was difficult to find complete project files, thereby making it difficult to document if monitoring was occurring or being tracked by regulatory staff.
- The research found that 41 to 78% of projects required maintenance; however, only 20 to 60% of projects complied with maintenance requirements.
- Studies in Washington and Oregon found that approximately half of projects received some regulatory follow-up.
- Two studies suggested that follow-up had a positive influence on the level of compliance and success for compensatory wetland mitigation projects.

How is compensatory wetland mitigation doing in Washington?*

Five studies of compensatory wetland mitigation have focused on projects in Washington State during the past decade[1]. The studies examined success, ecological functioning, permit compliance, and achievement of required wetland area, though not all studies looked at the same factors in the same way. The results suggest that compensatory mitigation in Washington is neither fully successful nor completely unsuccessful.

Most studies found that less than half of wetland compensation projects are fully effective. In the most recent and comprehensive evaluation of compensation projects, Johnson et al. (2002) found that 13% of compensatory wetland mitigation projects were fully successful and 33% were moderately successful. In western Washington, Storm and Stellini (1994) determined that 24% of compensation projects functioned well. In King County, Mockler et al. (1998) indicated that 3% of projects replaced lost wetland functions.

In terms of compliance, Johnson et al. (2000) determined that 29% of projects were in full compliance, while for King County Mockler et al. (1998) found that 21% of projects were meeting their required performance standards.

Kentula et al. (1992) examined Section 404 permit decisions for Washington from 1980 through 1986. Data indicated that permit decisions resulted in a wetland loss of 40 acres (16 ha). Johnson et al. (2002) determined that 24 acres (10 ha) of wetland were lost due to projects that did not successfully establish wetland area and the frequent use of existing wetlands for enhancement.

[1]All studies, except Kentula et al. (1992), sampled a sub-set of the applicable mitigation projects.
*Results have been simplified for this summary. Please refer to Sections 6.3 and 6.4 for complete information.

6.5 Types of Compensatory Mitigation

When discussing compensatory mitigation it is important to have a common understanding of the types of compensation that can be used to mitigate for wetland losses. This is difficult because various agencies and organizations often define types of compensation differently (Morgan and Roberts 1999). An added difficulty is that each type of compensation represents a range of activities on a continuum rather than a distinct procedure.

This section describes several types of compensatory mitigation:

- Restoration
- Creation
- Enhancement/exchange
- Preservation
- Mixed compensatory mitigation
- Wetland mitigation banking
- In-lieu fee programs

Definitions given to each of the mitigation types are discussed below, followed by a description of how frequently each type is used and its relative effectiveness.

6.5.1 Restoration

Of the types of compensation, restoration has the widest variety of definitions. The most general is the reestablishment of wetland conditions (i.e., area, functions, and values) at a location where they formerly existed but no longer exist (Johnson et al. 2000, Jones and Boyd 2000). Activities associated with this definition could include removing fill material, plugging ditches, or breaking drain tiles. Other definitions involve returning a site to some historic condition. The following are examples of other definitions.

- Re-establishing historic hydrologic processes (National Research Council 2001) or hydrogeomorphic (HGM) classes (Johnson et al. 2000). Activities associated with this definition typically involve removing a levee or breaching a dike to reconnect an area to the floodplain or to tidal influence.
- "Return of an ecosystem to a close approximation of its condition prior to disturbance (NRC 1992). Restoration requires knowledge of the wetland type prior to disturbance and has the goal of returning the wetland to that type" (Gwin et al. 1999).
- Returning an altered wetland "to a previous, although altered condition (Lewis 1990)" (Gwin et al. 1999).
- "The process, or the result of the process of returning an area or ecosystem to some specific former condition" (Munro 1991).

Perhaps as a result of the numerous definitions, confusion about what constitutes restoration versus other types of compensatory mitigation can occur in regulatory permits and mitigation plans. The last three definitions in the list above could just as easily describe enhancement activities. For example, planting trees in a degraded wet pasture, often considered enhancement, could be an attempt to return an ecosystem (the pasture) to an approximation of its prior condition (forested wetland).

In their study of compensatory wetland mitigation projects in Tennessee, Morgan and Roberts (1999) mentioned that several projects were classified as restoration. Based on the activities specified, however, enhancement would have been a more appropriate term. Similar confusion occurred between restoration and creation. As a result of this confusion, the effectiveness of restoration, as a type of compensation, is difficult to assess.

6.5.1.1 Use of Restoration

For compensatory mitigation, restoration is often cited as the highest priority or most recommended type of compensation "because it offers the highest probability of success (Kruczynski 1990, Kusler and Kentula 1990, USDA-SCS 1992)" (Morgan and Roberts 1999). In addition, the National Academy of Sciences recommended restoration over creation. "Restoration of wetlands has been observed to be more feasible and sustainable than creation of wetlands" (National Research Council 2001).

This emphasis on restoration is not reflected in the number of freshwater, compensatory restoration projects implemented on the ground. Restoration tends to be one of the least utilized types of compensation (Jones and Boyd 2000). In fact, two studies mentioned that none of the projects involved restoration (Shaich and Franklin 1995, Gwin et al. 1999). Most of the studies that specifically mentioned the number or percentage of projects using a particular type of compensation found that 20 to 30% of projects involved some restoration of wetland acreage (Morgan and Roberts 1999, Johnson et al. 2000, Johnson et al. 2002). Projects employing restoration as the sole form of compensation are even fewer (Shaich and Franklin 1995, Johnson et al. 2000, Johnson et al. 2002).

In a departure from the other studies, Holland and Kentula (1992) found that 65% of permits required restoration. However, 42% of the compensatory wetlands they looked at were estuarine or marine. If estuarine and marine projects are subtracted, the percentage of restored, freshwater wetlands is similar to the other studies.

Morgan and Roberts (1999) suggest that the lack of compensatory wetland restoration projects is due to the fact that "most suitable restoration sites are 'prior converted' farmland and because sizable acreages are being restored under the Wetland Reserve Program . . . sites available for compensatory mitigation may be limited." In Washington, however, the authors of Volume 1 believe that restoration is used infrequently because most wetland impacts are relatively small (less than 2 acres [0.8 ha]), and it is very difficult to find restoration opportunities for small sites that are not cost prohibitive. Restoration is typically most feasible and cost effective if done over a

large area. In addition, some regulatory requirements, particularly for local governments, direct applicants to provide compensation on-site, which often precludes an opportunity for restoration.

6.5.1.2 Effectiveness of Restoration

While it is widely stated that restoration is the most effective approach, the data to substantiate this claim are sparse. Studies indicate that there is a limited use of restoration for compensatory mitigation in freshwater wetlands. Thus, there is a substantial lack of data with which to evaluate its effectiveness as a type of compensation.

In Washington Johnson et al. (2000) found that one of three restoration projects was in full compliance. Johnson et al. (2002) found that one of two restoration projects established the required acreage of wetland and was fully successful. In Florida, Erwin (1991) found that restoration successfully established 88 acres (36 ha) more wetland area than was required. The limited existing data appear to suggest that when wetlands are restored, they are relatively effective at compensating for permitted losses.

6.5.2 Creation

It is generally agreed that creation involves establishing wetland conditions (area, functions, and values) in a location where wetland conditions previously did not exist (Johnson et al. 2000) or "that was not a wetland in the recent past (within the last 100-200 years) (Kruczynski 1990, Lewis 1990)" (Gwin et al. 1999). "Typically, a wetland is created by excavation of upland soils to elevations that will support the growth of wetland species through the establishment of an appropriate hydroperiod (Kruczynski 1990, Lewis 1990)" (Gwin et al. 1999).

Gwin et al. (1999) made a distinction between creating a wetland that is isolated from existing wetlands (creation) and creating a wetland that is immediately adjacent to an existing wetland, thereby enlarging the existing wetland (expansion). No other studies made this distinction.

The U.S. Army Corps of Engineers' Regulatory Guidance Letter -02-2 uses the term *establishment* rather than the previously accepted term *creation*. Federal agencies, as well as the Department of Ecology, have started using the term *establishment*. However, this document synthesizes studies and documents written before this regulatory guidance letter was produced. Therefore, this document uses the term *creation* rather than *establishment*.

6.5.2.1 Use of Creation

Seven studies discussed how frequently creation was required as compensation. All noted that at least 30% and in some cases more than half of compensatory wetland projects were created or involved some creation (Holland and Kentula 1992, Shaich and Franklin 1995, Gwin et al. 1999, Morgan and Roberts 1999, Johnson et al. 2000, Jones and Boyd 2000, Johnson et al. 2002).

6.5.2.2 Effectiveness of Creation

In Washington, Johnson et al. (2000) found that 10% of created wetlands were in compliance. Seventy percent of creation projects established the required acreage of wetland, and 60% of created projects were either fully or moderately successful (Johnson et al. 2002).

In other states, however, created wetlands did not perform as well. Creation projects failed to establish 527 acres (213 ha) of required wetland area in Florida (Erwin 1991). In Tennessee, Morgan and Roberts (1999) found, "Most creation projects…were only partially successful because they failed to develop wetland characteristics throughout… Problems with created wetlands were numerous and involved both site design and vegetation establishment."

The results on the effectiveness of creation are mixed. Though projects in Washington have poor compliance, other aspects of effectiveness are relatively good. However, other states found poor effectiveness for created wetlands. The data therefore suggest that further study is warranted.

6.5.3 Enhancement/Exchange

Enhancement involves modifying a specific structural feature of an existing degraded wetland to improve one or more functions or values based on management objectives (Gwin et al. 1999, Johnson et al. 2000). Enhancement typically consists of:

- Planting vegetation
- Controlling non-native, invasive species
- Modifying site elevations or the proportion of open water to influence hydroperiods

Gwin et al. (1999) defined exchange as:

> *Enhancement taken to the extreme (Kruczynski 1990), with most or all of the wetland converted from one type to a different type. For example, resource managers may intend to enhance habitat value for waterfowl by excavating an area of open water within an existing emergent marsh. However, if the open water area replaces the emergent wetland or a large proportion of it, wetland types have been exchanged.*

Because enhancement involves altering an existing wetland to compensate for the loss of other wetlands, the scientific literature mentions three main concerns regarding its use.

- Enhancement fails to replace lost wetland area (Shaich and Franklin 1995, Morgan and Roberts 1999). For this reason, the state of Michigan does not allow the use of enhancement for compensatory mitigation (Michigan Department of Environmental Quality 2000).

- Enhancement may fail to replace wetland functions, since "a positive change in one wetland function may negatively affect other wetland functions (Kruczynski 1990, Lewis 1990)" (Gwin et al. 1999). In addition, "there commonly is disagreement about whether or not the practice implemented actually enhances conditions at a site" (Morgan and Roberts 1999).

- Enhancement may result in a conversion of HGM and/or Cowardin classes, typically producing a compensation wetland without natural analogues (Shaich and Franklin 1995, Gwin et al. 1999, Johnson et al. 2002). When enhancement is used for compensation in such cases:

  A single Section 404 decision results in the destruction of the wetland for which the permit was issued, along with the conversion of a second wetland to a different, often atypical, HGM type. This 'double whammy' means that exchange [enhancement] *explicitly does not fulfill the objective of 'no-net-loss' of wetlands but, instead, ensures loss of wetland area, additional wetland disturbance, and changes in overall ecological function* (Gwin et al. 1999).

6.5.3.1 Use of Enhancement

Studies indicated that more than one-third of compensation projects used enhancement of existing wetlands as compensatory mitigation (Shaich and Franklin 1995, Gwin et al. 1999, Morgan and Roberts 1999, Johnson et al. 2000, Johnson et al. 2002).

6.5.3.2 Effectiveness of Enhancement

The effectiveness of enhanced compensation wetlands was evaluated by only two studies, both conducted in Washington. The researchers found less than 13% of enhanced wetlands were in complete compliance, while 56% of enhanced wetland projects met the requirement for acreage of compensation. (For projects that proposed to enhance existing wetlands, establishing the required acreage of wetland compensation entailed implementing the proposed actions to enhance the mitigation site.) Furthermore, none of the enhanced compensation wetlands were fully successful, while 89% were minimally or not successful (Johnson et al. 2000, 2002). For more information refer to Section 6.3.1 and Table 6-1.

Johnson et al. (2002) suggested two main reasons for the low level of success among enhancement projects.

- The enhancement project did not achieve the proposed vegetative structure, diversity, or both (the planted trees and shrubs did not survive or did not grow). Thus the project did not establish the required acreage of compensation, did not meet performance standards, or both.

- The enhancement project achieved the proposed structure/diversity, but despite this, it did not adequately compensate for the wetlands lost because the contribution of the enhancement to the performance of wetland functions was low.

The enhanced wetlands evaluated by Johnson et al. (2002) were all in the ground for less than eight years. Their study confirmed that for the projects they evaluated, eight years was not sufficient time to achieve the structural and species complexity of shrub and forested habitats. When structurally complex habitats are the goal of a compensatory mitigation design, studies continue to show that longer timeframes are necessary to begin to provide some of the attributes of those functions (National Research Council 2001). If structurally complex habitats are altered, it is possible to conclude that the delay in replicating those functions results in a prolonged temporal loss of functions on the landscape. This is equally true for projects proposing to restore or create wetlands.

Wetland creation vs. enhancement: Which contributes greater functions?

Johnson et al. (2002) determined that created wetlands were significantly more successful than enhanced wetlands. These researchers assessed the potential of compensation wetlands to perform wetland functions. They then determined how much the activities associated with the type of compensation contributed to, or improved, the level of wetland function. For creation/restoration projects it was assumed that if wetland conditions were achieved then the compensation activities were responsible for providing the assessed level of wetland functions. Enhanced wetlands performed some wetland functions prior to implementation of compensation activities. The authors believed it was important to determine how much enhancement activities contributed to, or improved, the level of performance of functions at a compensation wetland. The authors believed this was particularly important since enhancement, as a compensation tool, is based on improvement of wetland functions.

The study compared the contribution of created sites and enhanced sites for three function categories. Results indicated that over half of the created sites provided high or moderate contributions to wildlife habitat, water quality, and water quantity functions. Over half of the enhancement projects provided minimal to no contribution to wetland functions. The vast majority of enhancement actions were targeted at improving wildlife habitat functions. However, the enhanced wetlands were typically surrounded by development and lacked the buffers and connectivity necessary to improve habitat for most wildlife. In addition, most of the wetlands that were enhanced already provided some water quality functions. Thus, creation of wetlands provided a significantly greater contribution to the performance of water quality functions than enhancement of wetlands. Contribution to wetland functions was one element of overall success.

It is important to note that many created wetlands and some enhanced wetlands resulted in Cowardin and hydrogeomorphic (HGM) classes that were not typical for the landscape. This is discussed in more detail in Sections 6.8.2.2 and 6.8.5.1, respectively. Also, because enhancement provides less gain in function per acre than creation or restoration, replacement ratios are generally higher; refer to Section 6.6 for more information.

6.5.4 Preservation

Preservation means "the protection of an existing and well-functioning wetland from prospective future threats" (National Research Council 2001). Preservation, therefore, provides the opportunity to protect wetland areas that might otherwise be in jeopardy. Like enhancement, preservation does not produce any new wetland acreage; for that reason, some concerns have been raised regarding its use as compensation for permitted wetland loss.

- Preservation results in a net loss of wetland acreage.
- Preserved wetlands are generally not large enough to protect ecosystems and biodiversity over the long term (Whigham 1999).
- Preserved areas may not be checked by regulatory agencies to verify that they contain the specified acreage of wetland. For example, Morgan and Roberts (1999) observed that one of the larger preserved wetlands in their study was predominantly upland and "did not meet the criteria for being considered a jurisdictional wetland."

On the other hand, if an area can be verified as wetland, "Preservation of an existing wetland removes the uncertainty of success inherent in a wetland creation or restoration project and requires no construction to complete" (Washington State Department of Transportation 1999). Preservation, therefore, eliminates the risk of failure and temporal loss of wetland functions since the preserved area is already an existing wetland.

6.5.4.1 Use of Preservation

The studies generally found that preservation was required as compensation for less than one-quarter of projects (Holland and Kentula 1992, Morgan and Roberts 1999, Johnson et al. 2000, Jones and Boyd 2000). Preservation generated about 2% of the compensatory wetland acreage in a study from San Francisco, California (Breaux and Serefiddin 1999). A report from the Washington State Department of Transportation (1999) indicated that 76% of state transportation departments in the United States use preservation as at least one component of compensatory mitigation and 38% use it as a stand-alone form of compensation.

6.5.4.2 Effectiveness of Preservation

There is a general lack of information about the effectiveness of preservation. Only one study examined the effectiveness of preservation as a type of compensatory mitigation. In Washington, Johnson et al. (2000) determined that all four of the projects involving preservation as the sole form of compensation were in compliance. Compliance for preservation projects entailed verifying that the area was preserved and free from development and that a deed restriction or conservation easement was in place to legally protect the parcel from future development.

6.5.5 Mixed Compensatory Mitigation

Mixed projects involve more than one type of compensatory mitigation. For example, a common proposal in the Pacific Northwest entails enhancing an existing wetland and creating additional wetland area immediately adjacent to it. Mockler et al. (1998) observed, "most sites consist of creation—a small pool graded for open water and emergents—and enhancement, typically of wetland buffer." Mixed compensation, however, can also occur on separate sites, such as a created wetland adjacent to the development site and a preserved wetland some distance away.

Several studies identified mixed compensation projects (Mockler et al. 1998, Gwin et al. 1999, Johnson et al. 2000, Johnson et al. 2002). For their studies of compensation wetlands, Mockler et al. (1998) and Johnson et al. (2002) classified compensation wetlands according to their dominant type of compensation. However, some projects lacked sufficient information to make this determination, while other projects lacked dominance by any one type of compensation.

6.5.5.1 Use of Mixed Compensation Projects

In the six studies that discussed how frequently mixed compensatory mitigation was required, results ranged from 13% (Johnson et al. 2002) to 43% (Johnson et al. 2000). Most studies found that mixtures were used for less than a third of projects (Holland and Kentula 1992, Shaich and Franklin 1995, Gwin et al. 1999, Morgan and Roberts 1999).

6.5.5.2 Effectiveness of Mixed Compensation Projects

Only two studies, both from Washington, examined the effectiveness of projects utilizing a mixture of compensation types. Johnson et al. (2000) found that 32% of mixed projects were in compliance. Johnson et al. (2002) determined that all of the mixed projects were moderately successful.

6.5.6 Wetland Mitigation Banking

Mitigation banking is defined as "the practice of restoring, creating, enhancing, or preserving off-site wetland areas to provide compensatory mitigation for authorized impacts to wetlands" (Environmental Law Institute 2002). Wetland banking provides an alternative to traditional, concurrent, compensatory wetland mitigation, and its acceptance and use continue to grow.

Typically a public agency, organization, or private entrepreneur establishes a bank on a large area to be used to compensate for a number of smaller wetland impacts. Banks are generally established as compensation in advance of authorized impacts to wetlands at another site. One may conclude that this practice could provide advantages over traditional compensatory mitigation by reducing the temporal loss of wetland functions.

6.5.6.1 Use of Wetland Banking

Mitigation banking was used for about 7% of Section 404 permits in California issued from 1971 to 1987 (Holland and Kentula 1992). For permits issued from 1996 to 1998 which required mitigation, the Corps District of Norfolk, Virginia reported about 10% of projects purchased bank credits for use as compensation (Jones and Boyd 2000).

By the beginning of 1996, Brown and Lant (1999) determined that 68 banks had been established across the country, totaling nearly 41,000 acres (16,590 ha). A recent survey by the Environmental Law Institute (2002) determined that 219 banks had been approved across 40 states, totaling more than 139,000 acres (56,250 ha). Though 22 of the 219 banks have already sold all their eligible compensatory wetland acreage/credits, the remaining 197 banks were active, meaning they had credits/acreage that had not yet been purchased for use as compensation (Environmental Law Institute 2002).

Since wetland bank credits result from one or more of the previously mentioned types of compensation, the Environmental Law Institute (2002) investigated how frequently each type was used in mitigation banking. Results indicated that 78% of banks involved multiple types of compensation and that enhancement and restoration are the most commonly used. Of the banks that relied on a single type of compensation, about a third was restoration; another third was creation, while enhancement and preservation were each used on 16% of the banks.

6.5.6.2 Effectiveness of Wetland Mitigation Banks

Only one study has examined the effectiveness of wetland mitigation banks. Brown and Lant (1999) examined banks that had been established by the beginning of 1996. Overall, they found there would be a net loss of over 21,000 acres (8,450 ha) of wetland due to the use of enhancement and preservation at banks. The authors also discovered that eight banks did not provide the functions required or specified, while four banks used or sold more acreage for compensation of wetland loss than was eligible from the bank (in other words, the bank was overdrawn).

Wetland mitigation banking is increasingly being used to compensate for wetland losses. Yet the only study investigating the effectiveness of banks raises concerns about its use. Further study will therefore be critical to determine the level of compliance and success of mitigation banks in providing functions.

Please refer to Section 6.10.6 Mitigation Banking for more information on wetland banking as it relates to improving compensatory mitigation. In addition, the *Draft Programmatic Environmental Impact Statement: Washington State's Draft Rule on Wetland Mitigation Banking* (Driscoll and Granger 2001) contains a more in-depth discussion of the issues involved in mitigation banking (available at: http://www.ecy.wa.gov/biblio/0106022.html).

6.5.7 In-Lieu Fee Programs

In-lieu fee programs provide an additional option for compensatory mitigation. They allow permit applicants to compensate for wetland losses by paying a fee to a third party such as a government agency or conservation organization (U.S. General Accounting Office 2001, Environmental Law Institute 2002). The fees are intended to be used to restore, create, enhance, or preserve wetlands (U.S. General Accounting Office 2001).

Generally, in-lieu fee contributions are collected in advance of wetland losses. These funds are accumulated until they are sufficient to design and implement a wetland compensation project (Environmental Law Institute 2002).

6.5.7.1 Use of In-Lieu Fee Programs

A recent survey by the Environmental Law Institute (2002) determined there were 87 active in-lieu fee programs across 27 states. "Through fiscal year 2000, developers used the in-lieu-fee option to fulfill mitigation requirements for over 1,440 acres [583 ha] of adversely affected wetlands, and paid over $64.2 million to in-lieu-fee organizations" (U.S. General Accounting Office 2001).

6.5.7.2 Effectiveness of In-Lieu Fee Programs

Two studies discussed the effectiveness of in-lieu fee programs. However, neither study provided information on the level of compliance or ecological success of these programs.

A study by the U.S. General Accounting Office (2001) examined the effectiveness of in-lieu fee programs used by the U.S. Army Corps of Engineers (Corps) to compensate for wetland losses permitted through the Section 404 program. Of the 17 Corps districts using in-lieu fees, 65% did not require a specific timeframe for spending or obligating the fees received, and a few districts had not spent or obligated any funds though they had been collecting fees as compensation for wetland losses for at least three years (U.S. General Accounting Office 2001). The study found that three districts used the fees for research and/or education, rather than on-the-ground activities to compensate for wetland loss. In-lieu fee programs in 30% of the districts restored, created, enhanced, or preserved wetland acreage equal to or greater than the wetland acreage lost. The remaining districts either had used the fees to implement wetland activities that did not compensate for the wetland acreage lost, or they did not have any data (U.S. General Accounting Office 2001).

A study by the Environmental Law Institute found that 45% of in-lieu fee programs lacked the data necessary to determine their effectiveness. In-lieu fees replaced more wetland acreage than was lost in 56 programs, while "thirteen in-lieu-fee programs reported replacing fewer acres than had been impacted" (Environmental Law Institute 2002).

These studies paint a rather grim picture of the effectiveness of in-lieu fee programs as compensation for wetland loss. However, both in-lieu fees and mitigation banking can

provide a mechanism to compensate for regulated wetland impacts that are so small they currently do not require compensation, because compensation for such small wetland losses was not considered viable or practical (Shabman et al. 1993). In the year 2000 federal guidance on the use of in-lieu fee arrangements for compensatory mitigation was issued, while prior to this there were no federal requirements for in-lieu fee programs (Environmental Law Institute 2002). Further study will be needed to ensure that abuses of in-lieu fee compensation are not occurring.

6.5.8 Summary of Key Points

- The variety of definitions or criteria associated with types of compensatory mitigation has led to confusion in permitting and evaluating projects. For instance, comparing the effectiveness of one type of compensation with another is impossible when it is not clear if a project involved creation, restoration, enhancement, or some combination thereof.

- Restoration has been recommended as the "highest priority" method for compensation. Research in Washington has found that it is the least used, though one of three projects was in compliance and one of two projects was fully successful.

- Creation was used in one-third to one-half of compensation projects. In Washington, 10% of creation projects were in compliance, 60% were at least moderately successful. Studies from other states indicated that creation projects experienced major problems such as a failure to establish vegetation and produce wetland conditions.

- Enhancement was used for compensation in more than one-third of compensation projects. Research in Washington found that less than 13% of enhancement projects were in compliance. There were no fully successful enhancement projects, while 89% were minimally or not successful.

- The low level of success for enhancement projects was attributed to an inability to achieve the proposed vegetative structure/diversity, a minimal gain in functions, or both. This may partially be a factor of time: There will be continued temporal loss of some functions until young sites mature to more complex structural conditions.

- Two studies from Washington indicated that mixed compensation projects had a higher level of compliance than either creation or enhancement, and all mixed projects were moderately successful.

- Preservation can result in permanent protection of existing wetland resources, but compliance was found to be variable. One study found a large area of preserved wetland was actually predominantly upland habitat. However, a study in Washington found that 100% of preservation sites were in compliance.

- Studies of wetland mitigation banking and in-lieu fee programs focused on whether the goal of preventing the net loss of wetlands had been achieved on paper. The results indicated that a net loss of wetland area was occurring. A few banks were overdrawn, and some of the in-lieu fee programs had not used the money collected to implement compensation activities. No studies determined their effectiveness on the ground.

Does size influence the effectiveness of compensatory wetland mitigation projects?

Studies of the effect of wetland size on compensation projects revealed mixed results.

Two studies indicated that larger projects, which probably involved more planning and regulatory oversight, had a higher level of compliance (Brown and Veneman 2001) or success (Allen and Feddema 1996). Allen and Feddema (1996) noted that large projects (greater than 8.6 acres [3.5 ha]) resulted in a net gain of wetland acreage, while the smaller projects resulted in a net loss of wetland acreage. Though Brown and Veneman (2001) indicated larger projects had a higher level of compliance, larger projects were no more successful at replacing the plant communities or wildlife functions that were lost than the smaller compensation wetlands.

Two other studies determined that no statistically significant correlation existed between wetland size and compliance or success (Balzano et al. 2002, Johnson et al. 2002). Raw data from Johnson et al. (2002) implied that compensatory mitigation projects 5 acres (2 ha) or larger were less successful than smaller projects. Balzano et al. (2002) found that larger compensation wetlands tended to be more successful at establishing the required wetland acreage. However, this trend was attributed to one large site (over 40 acres [16 ha]) that established more wetland acreage than was required.

The Committee on Mitigating Wetland Losses determined that wetland size does affect wetland functions (National Research Council 2001). For example, "for water quality purposes, many small wetlands would be more effective than one large wetland covering the same area." The committee therefore concluded that "replacement area should be proportional to the area required to replace the functions lost" (National Research Council 2001).

6.6 Replacement Ratios

A replacement ratio, or compensation ratio, is an approach used to determine appropriate reparation for permitted wetland losses. Not all regulatory agencies use this approach. For example, the U.S. Army Corps of Engineers, Seattle District considers the needs for compensation on a project-specific basis rather than assigning replacement ratios.

The replacement ratio reflects the acreage of a particular type of compensatory mitigation (creation, restoration, enhancement, or preservation) required to make up for the loss of an acre of wetland (King et al. 1993, McMillan 1998). For example, a permitted loss of one acre may be compensated with two acres of restoration, thus requiring a 2:1 replacement ratio. The rationale for requiring more than 1:1 replacement for wetland impacts is provided in Section 6.6.1.

This section provides the following information:

- The rationale for using replacement ratios
- A summary of the literature regarding what replacement ratios are being required and if they are being achieved
- Some of the methods used to determine appropriate replacement ratios

6.6.1 Rationale for the Use of Replacement Ratios

When compensatory wetland mitigation was first required, the loss of an acre of wetland would simply require an acre of compensation (McMillan 1998). A simple 1:1 replacement ratio generally is no longer considered appropriate (Castelle et al. 1992a, King et al. 1993, National Research Council 2001) for the following reasons:

- **Risk of failure.** It is possible that compensation projects will not perform as proposed (King and Bohlen 1994) and may fail to compensate for wetland losses (Castelle et al. 1992a).
- **Temporal loss.** It may take anywhere from several years to several decades for a compensation project to achieve ecological equivalency (National Research Council 2001) and to develop the proposed/required wetland structures and/or functions (Castelle et al. 1992a).

Because of the risk of failure and temporal loss, "replacement ratios greater than 1:1 are used as a means of equalizing the tradeoff. While the goal is always to replace the lost functions at a 1:1 ratio, it is almost always necessary to increase the replacement acreage in order to accomplish this" (McMillan 1998).

A literature review performed by Castelle et al. (1992a) concluded that:

> *The risks of project failure and the time it takes for a created wetland to represent a fully functioning ecosystem should be factored into replacement ratios which exceed 1:1…*
>
> *Replacement ratios of 2:1 or greater are necessary to compensate for our current rate of failure to achieve permit compliance of basic wetland community structural objectives within attempted mitigation projects, neither of which are accurate measures of functional equivalency.*

An additional consideration is that there are many types of wetlands and various degrees of degradation. As a result, not all wetlands provide the same levels of functions or values. Replacement ratios, therefore, should take into account the type and quality of the wetland and the functions and values that would be lost. For example, the loss of a high-quality forested wetland would require a higher replacement ratio than the loss of a highly degraded wet pasture (Breaux and Serefiddin 1999).

Also, the type of compensation can influence the replacement ratio. Johnson et al. 2002 found that the use of enhancement not only results in a net loss of wetland area but provides a limited increase in wetland functions. Therefore, enhancement typically requires higher replacement ratios than restoration or creation (McMillan 1998).

Higher replacement ratios result in more area for compensatory mitigation, but unfortunately size does not guarantee success or quality. A study conducted by the National Academy of Sciences concluded that attempts to compensate for rare wetland types by requiring high replacement ratios yielded wetlands of a common type at a low ratio. Rather than replicating the rare wetland type, a more common wetland type was substituted. "In effect, the regulatory program may reassemble the landscape with a different habitat mix than the wetlands being lost" (National Research Council 2001).

6.6.2 Replacement Ratios Required and Achieved

Table 6-8 summarizes the overall or average replacement ratios that were required for compensatory wetland mitigation projects. A wide range of replacement ratios was required—from 0.66:1 to 5.9:1 (Kunz et al. 1988, Johnson et al. 2000). These are the extremes. The low end represents projects from the early to mid 1980s, when compensatory mitigation was still a relatively new idea. The higher ratios reflect more recent projects using predominantly enhancement and/or preservation, which typically require higher replacement ratios.

Between these extremes, the remaining studies noted ratios ranging from 1.5:1 to 2.7:1 (Wilson and Mitsch 1996, Morgan and Roberts 1999, Michigan Department of Environmental Quality 2000, Balzano et al. 2002, Johnson et al. 2002, Robb 2002).

Actual replacement ratios that were achieved for the projects studied are also shown in Table 6-8. None of the studies found that the required ratios had been realized. In fact, Balzano et al. (2002) determined that forested compensation wetlands achieved only 1/100th of an acre for every acre lost despite the fact that over 2 acres of forested wetland were required. Achieved ratios ranged from 0.7:1 to 1.9:1 (Wilson and Mitsch 1996, Morgan and Roberts 1999, Balzano et al. 2002, Johnson et al. 2002, Robb 2002).

As mentioned in the previous section, replacement ratios typically require greater than 1:1 replacement to factor in the risk of failure. Table 6-8 demonstrates the utility of this approach since all of the studies indicated that the achieved ratios were smaller than those required. All but one of the studies found the achieved ratios were greater than 1:1, though not by a substantial margin. But two of these studies included enhancement of existing wetlands.

Ratios are a tool to address the temporal loss of wetland functions and the historic failure of replicating wetland acreage and functions. The results indicate an inability of compensation projects to achieve their required replacement ratios. It is assumed that this inability reflects the same problems and shortfalls associated with compensation project success and compliance (see Section 6.4).

Table 6-8. Comparison of replacement ratios that were required and achieved.

Location of Study and Reference No.	No. of Projects Evaluated	Replacement Ratio Required	Replacement Ratio Achieved	Comments
Washington (Johnson et al. 2002)	24	2.2:1[a]	1.87:1 [a]	Enhancement accounted for 65% of the established acreage
Washington (Johnson et al. 2000)	45	5.9:1 [a]	NA	Acreage predominantly preservation and enhancement
Washington (Kunz et al. 1988)	35	0.66:1	NA	Corps and EPA data 1980 to 1986
Michigan (Michigan Department of Environmental Quality 2000)	76	1.82:1 (average)	NA	Required ratios ranged <1:1 to >5:1; study did not include enhancement
Indiana (Robb 2002)	31	2.5:1	1.1:1	Achieved ratios for specific Cowardin classes ranged from 0.48:1 for PFO to 45:1 for POW; study did not include enhancement
Ohio (Wilson and Mitsch 1996)	4 (5)	1.5:1 (1.7:1) [a]	1.4:1 (0.7:1) [a]	Study reviewed 5 projects, results and conclusions focus on 4; parentheses reflect results for all 5
New Jersey (Balzano et al. 2002)	75	1.8:1 (average) 2.04:1 PFO 2.78:1 PSS 1.85:1 PEM 1.07:1 POW	0.78:1 (average) 0.01:1 PFO 0.91:1 PSS 1.29:1 PEM 0.28:1 POW	Sites proposing POW did not achieve the required acreage. However, POW was on sites that did not propose to have open water; thereby resulting in three times more POW acreage than required
Tennessee (Morgan and Roberts 1999)	47	2.7:1	1.9:1	Ratio = 0.88:1when enhancement and preservation are excluded

NA = not available

PFO = palustrine forested; PSS = palustrine scrub-shrub; PEM = palustrine emergent; POW = palustrine open water

[a] Calculated from data provided.

6.6.3 Approaches for Determining Replacement Ratios

King et al. (1993) proposed a framework for calculating replacement ratios, "based on the idea that compensatory mitigation involves trading one form of environmental capital for another and that full compensation requires increases in environmental functions and values from the compensation wetland that are sufficient to make up for the decline in functions and values resulting from the loss of existing wetland." The authors mentioned five parameters to consider when determining an appropriate replacement ratio.

- The pre-existing level of wetland function per acre at the site proposed for wetland compensation. In the case of enhancement, this ensures that an applicant does not get mitigation credit for functions that were already being provided by a pre-existing wetland.
- The maximum level of function anticipated to be provided by the wetland compensation project.
- The number of years after construction that will be required for the wetland compensation project to reach its anticipated or sustainable level of function.
- The number of years between the loss of the original wetland and the completion of construction of the compensation wetland (temporal loss). Mitigation could be done concurrent with impacts, in advance, or delayed after impacts occur.
- The likelihood that the project will not achieve its anticipated level of function.

King et al. (1993) suggested entering the values for each of the five parameters into an analytic model that then calculates an appropriate compensation ratio for the project-specific information provided. King and Bohlen (1994) provided easy to use tables of replacement ratios that would result from a variety of values for the five parameters identified above. Using parameters comparable to King et al. (1993) for determining appropriate compensation, Rheinhardt et al. (1997) described an approach based on function assessment. The authors proposed the following steps.

1. Develop a function assessment method for the specific regional conditions, including identification of reference wetlands.

2. Assess wetlands proposed to be lost, thereby determining the level of each wetland function that will be lost.

3. Assess potential compensatory mitigation sites to evaluate their current level of function and predict future conditions and levels of function that would result from mitigation activities within the timeframe required for regulatory monitoring.

4. Calculate ratios for compensation for each function "by dividing the degree to which a function is reduced through project alteration by the degree to which a function is increased through restoration" (Rheinhardt et al. 1997).

The ratio "varies among functions and is influenced by (1) the magnitude to which any given function occurs at a project site both before and after the site is altered, (2) the magnitude to which any given function occurs at a compensatory mitigation site both before and after restoration is applied, and (3) the rate at which any given function is restored" (Rheinhardt et al. 1997). The goal of this approach is not just to ensure no net loss of wetland functions but also to restore wetland ecosystems (Rheinhardt et al. 1997).

In contrast, Breaux and Serefiddin (1999) argue that "there has not been any single, universally accepted assessment procedure to determine wetland functions and values (Kusler 1997)." As a result they suggest that "the quantitative measure of area provides a degree of certitude that should be taken advantage of" (Breaux and Serefiddin 1999). In other words, assessing or determining the level of functions provided by a wetland can be time-consuming to near impossible, while acreage provides an easy measurement. The authors mention a few conditions that may require greater than 1:1 replacement ratios (for example 2:1 or 3:1):

1. *If it is determined that the area lost includes functions and values of high quality…*

2. *If… the replacement area is outside the watershed, sub-watershed, or county;*

3. *If the replacement area involves a high risk of failure or uncertain outcome,*

4. *If there are high temporal losses…*

5. *If the habitat loss is likely to be substantially greater than the creation of new habitat; or*

6. *If the connection between two wetland sites is severed or a large site is divided* (Breaux and Serefiddin 1999).

Robb (2002) also proposed using an acreage-based system for determining appropriate replacement ratios. However, where the previous studies did not base ratios on the type of wetland, his system focused on developing replacement ratios for each Cowardin class. This approach resulted from a delineation of 31 compensatory mitigation sites in Indiana. Robb (2002) compared the required acreage of each Cowardin class with the acreage that was established. For example, results indicated that 71% of the required acreage of palustrine forested wetlands was not established (a 71% rate of failure). The ratio recommended to overcome this failure was calculated by dividing the required acreage by the acreage actually established. Using these data, the ratio for palustrine forested wetlands should therefore be 3.5 acres of compensation for every acre of wetland lost. The rationale was that for every 3.5 acres constructed that were intended to be palustrine forested wetland, 1 acre would actually become forested wetland. Proposed ratios for other wetland types included:

- 1.8:1 for scrub-shrub
- 7.6:1 for wet meadow
- 1.2:1 for shallow marsh
- 1:1 for open water

Robb (2002) conceded that his study did not consider the quality of the compensation wetlands or whether they replaced the functions lost. The author mentioned that more regulatory follow-up could result in more successful projects and therefore lower replacement ratios.

6.6.4 Summary of Key Points

- Replacement ratios provide a means of taking into account the potential failure and temporal loss of functions as well as the potential change in acreage or functions to be provided by the compensation project.
- Several methods are available to calculate replacement ratios on a case-by-case basis. Examples of some of the criteria used to determine ratios include the functions proposed to be provided at the compensation site, the functions anticipated to be lost at the impact site, size, landscape position, and relative chance of success.
- Required replacement ratios vary from one state to another, based on the type of compensation proposed, and based on project-specific circumstances.
- Studies found that compensation projects did not achieve their required replacement ratios. In some cases this resulted in less than 1:1 acreage replacement.

6.7 Replacement of Wetland Acreage

This section summarizes the results of studies examining whether compensatory wetland mitigation is replacing the acreage of authorized wetland losses. Replacement of wetland acreage is similar to "no net loss," which refers to a goal for the nation and Washington State to ensure there will be no overall net loss in acreage and function of the remaining wetland resource base (The Conservation Foundation 1988, McMillan 1998). The no-net-loss goal, however, "does not mean that no further wetlands will be lost; rather, that mitigation and non-regulatory restoration will offset wetland losses" (McMillan 1998). Replacement of wetland acreage, on the other hand, focuses on wetland losses and gains associated with compensatory wetland mitigation.

Replacement of wetland acreage provides a measurable and consistent method for evaluating and comparing the effectiveness of compensatory mitigation programs (Kusler 1988). The scientific literature contained two types of information on this topic.

- Studies that evaluated how well permitting programs (e.g., Section 404) achieved replacement of wetland acreage. Most of these studies used information from permit files and databases.

- Studies that evaluated how well compensation projects achieved the replacement of wetland acreage on the ground. These studies were conducted in the field and typically involved the delineation of wetland boundaries.

6.7.1 Programmatic Evaluations of Acreage Replacement

Programmatic evaluations, in contrast to most of the studies mentioned thus far, are not concerned with the effectiveness of individual compensatory mitigation projects. Instead, programmatic evaluations focus on whether a permitting agency or permit program is requiring sufficient wetland acreage compensation to replace the authorized wetland losses occurring over a specified time.

In a programmatic evaluation, wetland acreage replacement is determined by comparing the acreage of wetlands lost, or adversely altered, with the acreage of wetlands required for compensatory mitigation in a specific geographic area. These evaluations typically rely on information from permit files and databases, rather than verification of on-the-ground, as-built conditions.

Five studies examined the effectiveness of wetland permitting and compensatory mitigation programs (Table 6-9). The earliest study reviewed Section 404 permit data from Washington, 1980 to 1986, and Oregon, 1977 to 1987, "to describe how permit decisions affect the wetland resource" (Kentula et al. 1992). Results indicated that in Washington 39 acres (16 ha) of wetland were not replaced, while in Oregon 79 acres (32 ha) of wetland were not replaced. The authors also observed, "In Washington, approximately 3 percent of the permits issued required compensatory mitigation" (Kentula et al. 1992).

The results of this study should be considered within the context of the Seattle District Corps of Engineers regulatory program in the early 1980s. The authors of Volume 1 observed that in the early 1980s compensatory mitigation, when it was required, was only required for projects that triggered an individual permit. The threshold for wetland fill under a Nationwide Permit 26 (a general permit for headwaters and isolated waters discharges) was 10 acres (4 ha), therefore an individual permit was only required for projects with greater than 10 acres of wetland fill. Fill of 10 acres or less in isolated wetlands was permitted outright. It is therefore possible to conclude that the 40 acres of wetland identified by Kentula et al. (1992) as "not replaced" very likely represents but a fraction of the total acreage of permitted wetland losses that were not compensated for at that time.

A study of Section 404 permitting from southern California noted that 8 acres (3 ha) of wetland were not replaced (Allen and Feddema 1996). The study also determined that "freshwater wetlands are experiencing a disproportionately greater loss of area and that riparian woodland wetlands are most often used in mitigation efforts. The net result of these accumulated actions is an overall substitution of wetland types throughout the region" (Allen and Feddema 1996).

Two of the remaining studies generally found that permitting programs required a net gain from compensatory mitigation (Table 6-9). Gains in acreage ranged from about 47 acres (19 ha) (Torok et al. 1996) to nearly 197 acres (80 ha) (Holland and Kentula 1992). However, the study of the effectiveness of the New Jersey Freshwater Wetlands Protection Act (Torok et al. 1996) mentioned compensatory mitigation acreage only for individual permits. It was not clear from the article if any of the 3,003 general permits, resulting in over 600 acres (243 ha) of wetland loss, required any compensatory mitigation. Furthermore, Holland and Kentula (1992), in their evaluation of Section 404 permitting in California, noted that data on acreage of impacts and compensation were lacking in about 40% of the permit files.

The fifth study focused on the Norfolk Corps District (Jones and Boyd 2000). The authors indicated that new wetland acreage produced by creation or restoration did not fully replace the permitted wetland losses, thereby resulting in a loss of about 260 acres (105 ha) (Jones and Boyd 2000). However, preservation, mitigation bank credits, and substantial in-lieu fee contributions provided additional compensation. If acreages from all types of compensatory mitigation are included, the authors assumed there was a gain of at least 1,500 acres (607 ha). Despite the fact that only 24% of the permits required compensation, the authors concluded that replacement of wetland acreage was achieved, at least on paper (Jones and Boyd 2000).

The results (Table 6-9) indicate that since the early 1980s, permitting programs have required an increasing amount of acreage to compensate for wetland losses. It can be inferred that permits from the mid-1980s did not require the replacement of acreage for wetland losses, whereas permits from the mid- to late 1990s appear to have required replacement of wetland acreage.

Table 6-9. Permitted wetland loss compared to required wetland compensation.

Location of Study	No. of Permits	Wetland Area Lost	Area of Compensation Required	Comments
Washington (Kentula et al. 1992)	35	152 acres (61.4 ha)	112 acres (45.5 ha) created	Section 404 permits 1980-1986
Oregon (Kentula et al. 1992)	58	183 acres (73.9 ha)	103 acres (41.8 ha) created	Section 404 permits 1977-1987
California (Holland and Kentula 1992)	324	2,907 acres (1,176.3) ha	3,103 acres (1,255.9 ha)	Section 404 permits 1971-1987; data on acreages was often lacking

Location of Study	No. of Permits	Wetland Area Lost	Area of Compensation Required	Comments
California/ southern (Allen and Feddema 1996)	75	199 acres (80.5 ha)	191 acres (77.3 ha) completed	Section 404 permits 1987-1989; permits required 276 acres (111.6 ha) of compensatory mitigation
Norfolk Corps District (Jones and Boyd 2000)	1692	863.8 acres (349.6 ha)	538.6 acres created (218.0 ha) 65.5 acres restored (26.5 ha) 1,537.2 acres preserved (622.1 ha) 200.8 bank credits $2,574,966 in lieu fee	Section 404 permits 1996-1998
New Jersey (Torok et al. 1996)	3003 (107)	602 acres (243.8 ha) *164 acres (66.5 ha)*	NA *171 acres (69.2 ha) created;* *41 acres (16.5 ha) restored*	New Jersey Freshwater Wetlands Protection Act permits 1988-1993. *Numbers in italics are individual permits; all other numbers are state general permits.*

6.7.2 Project-Specific Evaluations of Acreage Replacement

Studies that examined the effectiveness of compensation projects often assessed whether the projects achieved replacement of wetland acreage. The assessment generally involved determining how much wetland acreage the compensation projects provided. The wetland compensation acreage produced on the ground was then compared to the acreage of wetland loss associated with those projects. If the compensation acreage was less than the wetland acreage lost, a net loss of wetland occurred. Seven studies analyzed compensatory wetland mitigation project data to determine whether replacement of wetland acreage was achieved.

Four studies either focused on creation or restoration, or they did not mention the type of compensation. The studies noted that the acreage of wetland compensation was less than the acreage of wetland loss by as much as 34%, thereby resulting in a net loss of up to 8 acres (3 ha) (Gwin and Kentula 1990, Allen and Feddema 1996, Wilson and Mitsch 1996). However, a study conducted for the South Florida Water Management District found that creation and restoration activities resulted in 106% of the wetland acreage lost—a net gain of almost 65 acres (26 ha) of wetlands (Erwin 1991).

One issue that emerges when considering replacement of wetland acreage is the use of enhancement and preservation as wetland compensation. Three studies noted that enhanced or preserved wetlands accounted for 45 to 65% of the acreage of compensation (Shaich and Franklin 1995, Morgan and Roberts 1999, Johnson et al. 2002). In Washington nearly two-thirds of the established acreage of compensation involved

enhancing existing wetlands, while creation and restoration of wetland area replaced only 65% of the permitted wetland losses (Johnson et al. 2002).

Some authors discounted the acreage provided by enhancement and preservation. Enhancement and preservation are often not included in determining net loss or gain because neither type of compensatory mitigation produces any new wetland acreage (Breaux and Serefiddin 1999). When acreage provided by enhancement and preservation are disregarded, three studies found wetland losses of 22, 11, and 24 acres (9, 4, and 10 ha) respectively (Shaich and Franklin 1995, Morgan and Roberts 1999, Johnson et al. 2002). This equaled 58, 12, and 41% of the authorized wetland losses, respectively (Shaich and Franklin 1995, Morgan and Roberts 1999, Johnson et al. 2002).

6.7.3 Summary of Key Points

- Programmatic evaluations have documented an increase in the acreages of wetland compensation required since the early 1980s. However, the acreage of wetland replacement may include preservation, enhancement, or both.
- Project-specific data revealed that compensation wetlands did not replace the acreage of wetlands that were lost. Even larger losses occurred if the acreages of enhancement and preservation were discounted.

6.8 Functions and Characteristics Provided by Created, Restored, or Enhanced Wetlands

This section describes the functions and characteristics provided by wetlands created, restored, or enhanced for compensatory mitigation and non-regulatory projects.

- The capacity of created and restored wetlands to provide wildlife habitat for invertebrates, amphibians, and birds. Wildlife habitat was evaluated through direct observations or evidence of wildlife use, the presence of structural indicators, or comparison to reference wetlands.
- The ability of created, restored, or enhanced wetlands to develop plant communities and vegetative characteristics. Studies involved comparisons with reference wetlands and investigations of factors affecting vegetation.
- The importance of soil conditions, particularly as they relate to establishing vegetation and improving water quality. Soil properties of created and restored wetlands were compared with reference wetlands.
- The ability of created and restored wetlands to provide water quality functions.
- The importance of water regime and how the creation and enhancement of compensation wetlands can result in atypical water regimes.

The scientific literature indicated that the ability of compensatory wetland mitigation projects to perform wetland functions is not noticeably different from that of non-regulatory restoration or creation projects. Newly implemented wetland sites face similar challenges and develop in similar ways regardless of whether they were legally required or voluntarily initiated.

Refer to Chapter 2 of this document for a discussion of the functions that wetlands provide.

In Section 6.8, use of the terms "**significant**" and "**significantly**" implies statistical significance that was determined by the authors of the specific study being discussed.

6.8.1 Wildlife Habitat

Most articles focused on the ability of a created or restored wetland to provide habitat for one specific guild or group of animals, such as invertebrates, amphibians, or birds. Information on other habitat functions provided by created or restored wetlands was lacking.

6.8.1.1 Invertebrates

Several studies have compared the invertebrate communities of created or restored wetlands with those of reference wetlands. Most of these determined that reference wetlands were more diverse, had greater taxon richness, or had higher density of species than created or restored sites (Brown et al. 1997, McIntosh et al. 1999, Fairchild et al. 2000, Dodson and Lillie 2001). One study, however, found "no convincing differences" in fly (dipteran) densities between created and reference wetlands (Streever et al. 1996). None of these studies were conducted in the Pacific Northwest. However, the results should be broadly applicable to wetlands anywhere.

The age of the wetland, or the amount of time elapsed since restoration occurred, was an important factor influencing invertebrate taxon richness, abundance, and/or diversity (Brown et al. 1997, Fairchild et al. 2000, Dodson and Lillie 2001). For example, "insects with aerial dispersal capability rapidly colonized the restored habitats, but some less mobile forms (non-insects and some hemipterans [true bugs]) either colonized more slowly or not at all" (Brown et al. 1997). Dodson and Lillie (2001) determined that a newly restored site would require 6.4 years for the zooplankton taxon richness to resemble that of a minimally disturbed reference wetland.

The growth and development of vegetation also appears to affect invertebrate communities (Chovanec 1994, Brown et al. 1997, Chovanec and Raab 1997, McIntosh et al. 1999, Fairchild et al. 2000). For example, certain predatory groups of beetles were early colonists at young sites with limited development of vegetation, while herbivorous beetle groups occurred at older sites after specific types of vegetation had developed (Fairchild et al. 2000). McIntosh et al. (1999) concluded, "wetlands at different

successional stages may contain very distinct aquatic macroinvertebrate assemblages which may be important to the food web and other functional processes of wetlands."

6.8.1.2 Amphibians

The amphibian habitat present in created or restored wetlands has been compared with that of reference wetlands in several studies. On the east slope of the Cascade Range in the Teanaway and lower Swauk River drainages of Kittitas County, Quinn et al. (2001) found no difference in species richness of amphibians between created and reference wetlands, "although sample sizes may have been too small for differential species-use patterns to emerge." Other authors determined that created and restored wetlands differed from reference wetlands in terms of amphibian community structure, species richness, or stomach content (Bursey 1998, Lehtinen and Galatowitsch 2001, Pechmann et al. 2001).

Though created or restored wetlands provide habitat for some amphibian species, conditions within the wetland and conditions outside the wetland may limit productivity, dispersal, colonization, or all three. Conditions within a wetland that appear to affect amphibian communities include hydroperiod, substrate, presence of emergent vegetation, presence of fish, and the availability of an invertebrate prey source (Bursey 1998, Baker and Halliday 1999, Monellow and Wright 1999, Pechmann et al. 2001).

Conditions outside of a restored or created wetland that affect amphibian communities include distance to other wetlands, connectivity between habitats, and the land use of the surrounding terrestrial habitats (Baker and Halliday 1999, Monellow and Wright 1999, Lehtinen and Galatowitsch 2001, Pechmann et al. 2001). For example, Baker and Halliday (1999) observed that two species of amphibians dispersed to new ponds only if they were within 1,312 feet (400 m) of an existing pond, while two other species colonized new ponds up to 3,117 feet (950 m) from an existing pond.

Monellow and Wright (1999) concluded, "The interconnectiveness of amphibian habitat is an essential element in sustaining amphibian populations because it allows amphibians to overcome large population fluctuations and recolonize areas where populations have been extirpated."

Lehtinen and Galatowitsch (2001) found that the wetlands restored in urban areas had the lowest amphibian species richness. However, authors of a study of wetlands created in a recreational area in an intensively used urban site near Vienna, Austria observed all seven of the amphibian species known to occur in the area. As many as six species were breeding (Chovanec 1994).

6.8.1.3 Birds/Waterfowl

All of the studies that examined the ability of created or restored wetlands to provide habitat for birds focused on non-regulatory projects. Therefore this section does not contain information on the ability of compensatory wetland mitigation projects to provide habitat for birds. However, the information is still relevant based on the similarity of

results among compensatory and non-regulatory projects for the other studies of functions. None of the studies cited below were conducted in the Pacific Northwest.

Studies comparing bird use of created or restored wetlands and reference wetlands demonstrated variable results, perhaps indicating that site-specific conditions influence bird use. For example, two studies found no difference in bird abundance between restored and reference wetlands (Brown and Smith 1998, Ratti et al. 2001), while two other studies determined that reference wetlands had greater bird species richness and abundance (Delphey and Dinsmore 1993, Dobkin et al. 1998). Brown and Smith (1998) found no difference in bird abundance or the number of bird species observed. However, they did determine that the bird communities differed by a statistically significant margin and that density was greater at reference wetlands (Brown and Smith 1998). Regardless of the findings for bird populations in general, two studies noted that ducks had similar or greater abundance, species richness, or density at created and restored wetlands (Delphey and Dinsmore 1993, Ratti et al. 2001).

In the literature, the main factors that appeared to affect wetland use by bird populations were:

- The percent cover of emergent vegetation (Belanger and Couture 1988, Hemesath and Dinsmore 1993, VanRees-Siewert and Dinsmore 1996)
- The density and abundance of invertebrates (Belanger and Couture 1988, Cooper and Anderson 1996)

Though the age of the wetland did not directly affect overall bird populations at created and restored wetlands, VanRees-Siewert and Dinsmore (1996) noted that the richness of breeding bird species was significantly greater at older restoration sites. The composition of the bird community changed with age. Both of these effects were associated with an increase in the emergent vegetation in older wetlands.

6.8.2 Plants

6.8.2.1 Comparisons with Reference Wetlands

This section discusses studies that compared the vegetation of created and restored wetlands to that of reference wetlands. The studies examined a variety of parameters in a number of states and found variable results. Only one study determined that there was no difference in vegetation between created/restored and reference wetlands (Brown 1991). Two studies were conducted in the Pacific Northwest.

In the metropolitan area of Portland, Oregon, reference wetlands differed significantly from mitigation wetlands in terms of floristic composition. Mitigation wetlands had higher overall plant species richness, higher average percentage of native species, and significantly higher average occurrence of introduced and invasive/introduced species than reference wetlands (Magee et al. 1999).

Another study was conducted in the northwestern Great Basin on land that had previously been grazed by cattle. The study found that "sedge cover, forb cover, and foliage height diversity of herbs were greater" on reference plots, in which livestock had been excluded for more than 30 years. "[B]are ground, litter cover, shrub cover, and shrub foliage height diversity were greater" on restored plots, in which livestock grazing pressure had been removed prior to commencement of the study (Dobkin et al. 1998). During the four-year study period, restored plots experienced an increase in grass, forb, rush, and cryptogamic cover, but sedge cover did not change. The authors concluded, "the lack of change in sedge and shrub cover on open [restored] plots suggests that restoration to a sedge-dominated meadow will not happen quickly" (Dobkin et al. 1998).

Restored prairie pothole wetlands were found to lack low prairie and wet meadow zones that reference wetlands possessed. Restored wetlands had significantly higher richness of submersed aquatics and greater coverage by mudflat and open water (Delphey and Dinsmore 1993, Galatowitsch and van der Valk 1995, Galatowitsch and van der Valk 1996). The researchers concluded that restored wetlands are not likely to develop the sedge meadow and wet prairie zones present in reference wetlands (Galatowitsch and van der Valk 1995, VanRees-Siewert and Dinsmore 1996).

Other authors determined that reference wetlands exhibited greater percent cover by wetland species. However, created wetlands had species richness that was equal to or greater than reference wetlands (Moore et al. 1999). Restored wetlands had significantly lower wetland index values (indicating that wetland species were providing more of the total vegetative cover) than reference sites (Brown 1999).

One could hypothesize that created and restored wetlands have greater vegetation species richness due to the level of disturbance associated with creation and restoration and the broad range of niches created on a new site. For example, a newly created or restored site is like a *tabula rasa* (a blank slate) upon which species will be planted (installed or seeded), species from the previous habitat on the site will re-emerge, and species adapted to disturbance will colonize.

6.8.2.2 Cowardin Classes Provided by Compensatory Mitigation Wetlands

Cowardin class refers to a method used to categorize wetlands based on the dominant type of vegetation (Cowardin et al. 1979), as well as other factors. The main Cowardin classes used to categorize freshwater wetlands are:

- Emergent
- Scrub-shrub
- Forested
- Aquatic bed
- Open water (though not technically a Cowardin class, open water is often used to map and describe unvegetated areas of inundation)

Several studies evaluated compensatory wetland mitigation sites to determine which Cowardin classes were being established. Nearly all of these studies found that compensatory mitigation resulted in more acreage of open water/aquatic bed/deep marsh than was originally lost or required (Kentula et al. 1992, Shaich and Franklin 1995, Bishel-Machung et al. 1996, Magee et al. 1999, Cole and Brooks 2000, Michigan Department of Environmental Quality 2000, Balzano et al. 2002, Johnson et al. 2002, Robb 2002).

For example, in Washington State over 16 acres (6 ha) of open water/aquatic bed wetlands were gained (Johnson et al. 2002). In the Portland metropolitan area of Oregon, 29 acres (12 ha) of open water were gained (Shaich and Franklin 1995), and Indiana gained over 3 acres (1 ha) of open water/deep marsh/aquatic bed (Robb 2002). Compensatory wetland mitigation projects in New Jersey generated 50 acres (20 ha) more open water than was required (Balzano et al. 2002).

Results for other Cowardin classes were more variable. For example, four studies noted either a loss of forested wetland area (4 to 8 acres [2 to 3 ha]) or an inability to establish this wetland class (Shaich and Franklin 1995, Bishel-Machung et al. 1996, Brown and Veneman 2001, Balzano et al. 2002, Robb 2002). On the other hand, a study from Washington State observed a net gain of over 12 acres (5 ha) in forested/scrub-shrub wetlands (Johnson et al. 2002).

Additional variability occurred in the balance of emergent wetlands. Two studies from the Pacific Northwest noted a loss of 35 to 51 acres (14 to 21 ha) for emergent wetlands due to their conversion to other Cowardin classes (Shaich and Franklin 1995, Johnson et al. 2002). Studies from other states, meanwhile, found that emergent wetlands were established more successfully than other wetland classes (Bishel-Machung et al. 1996, Brown and Veneman 2001, Balzano et al. 2002). Though the studies did not mention whether the emergent wetlands were dominated by native vegetation, Brown and Veneman (2001) noted "plant communities in replicated wetlands differed significantly from those in wetlands they were designed to replace" in terms of the number and percent cover of species in general and the number and percent cover of wetland species.

Compensatory mitigation may often result in a different wetland type compared to what was lost (Shaich and Franklin 1995, Balzano et al. 2002, Johnson et al. 2002, Robb 2002). For example, if an open-water pond was provided as compensation for an authorized impact to a wetland pasture, a change in wetland type occurred. If the compensatory mitigation was enhancement and involved constructing an open water pond in another wetland pasture, a second change in wetland type occurred.

The studies examining changes in Cowardin classes at compensation wetlands found a net increase in open water/aquatic bed habitats (Shaich and Franklin 1995, Balzano et al. 2002, Johnson et al. 2002, Robb 2002). Though the reasons for this change are not clear for all studies, several studies indicated that open water/aquatic bed resulted from an inability to establish the proposed Cowardin class (Balzano et al. 2002, Robb 2002). One could assume that another reason may be that open water is relatively easy to establish given adequate hydrologic conditions. Furthermore, the authors of Volume 1 have

observed situations in which the wetland mitigation design was intended to maximize a limited space by providing a variety of habitat niches, and open water is often considered a key habitat niche for waterfowl. Therefore, it is possible to conclude that regulatory decisions may have been biased toward the construction of more open water/aquatic bed/emergent wetland complexes in order to achieve an enhancement of functions in a limited space.

Studies from Washington and Oregon reported a net loss of emergent wetlands (Shaich and Franklin 1995, Johnson et al. 2002). However, many wetlands in the Puget Lowlands of Washington and the Willamette Valley of Oregon that are classified as emergent are wet pastures dominated by non-native grasses. Johnson et al. (2002) noted that 90% of the emergent acreage lost or converted was pasture dominated by non-native species. It can be assumed that much of the current area of emergent pasture may historically have been forested wetland. Therefore, one can conclude that converting pastures into other wetland types with a greater diversity of hydroperiod and more structural complexity, such as forested wetlands, may represent an opportunity for a net increase in wetland functions over time, compared with leaving the wet pastures unchanged.

6.8.2.3 Factors Affecting Plants

Several major factors influencing wetland vegetation have emerged from the literature:

- Soil and soil disturbance
- Age of the wetland
- Competition and non-native vegetation
- Seed or plant source
- Human manipulation

The studies summarized in this section looked at different parameters in different types of wetlands across the country; therefore, the results are highly variable.

Soil and Soil Disturbance

Five studies indicated that soil conditions at the created or restored wetlands influenced vegetation composition (Brown 1991, Ashworth 1997, Brown and Bedford 1997, Stauffer and Brooks 1997, Brown 1999). Three of these studies discussed the positive effects of adding salvaged or donor hydric soil to created or restored wetlands. Benefits included increased species richness (Brown 1991, Stauffer and Brooks 1997) and significantly higher number and percent cover of wetland species (Brown and Bedford 1997). Stauffer and Brooks (1997) concluded that more organic matter in the hydric soil improved the retention of moisture and nutrients, thereby helping to increase plant cover, density, and species richness. Another study, involving dike removal to restore a site, observed that disturbance of the soil resulted in vegetation dominated by cattails (Brown 1999).

Age of the Wetland

The effect of age on the vegetation of created and restored wetlands was noted in various studies (Reinartz and Warne 1993, Magee et al. 1999, Moore et al. 1999). Created and restored wetlands less than three years old differed, in terms of floristic composition, from sites three years and older (Reinartz and Warne 1993, Magee et al. 1999). Older sites had higher mean total plant cover and mean cover of native wetland species (Reinartz and Warne 1993). Moore et al. (1999) found that age, in addition to sedimentation, resulted in:

- A decrease in open water and water depth
- An increase in emergent and woody cover
- An increase in the number of plant species
- An increase in wetland vegetation species richness

In western Washington, Celedonia (2002) investigated the age at which canopy convergence occurs. The study found that "aerial [woody] cover increases with age until year 8 and remains constant into years 10-11." The author noted, "80% cover is generally achieved by year 8, and perhaps as early as year 7." The study found that the most abundant species in terms of frequency and cover were red alder (*Alnus rubra*), willows (*Salix spp.*), black cottonwood (*Populus balsamifera*) and red osier dogwood (*Cornus sericea*). In addition, Celedonia (2002) found that native woody cover was strongly correlated with the density of stems greater than 6.5 feet (2 m) tall, such that percent cover increased as stem density increased up to about 2,100 stems per acre. Sites with densities higher than 2,100 stems per acre generally had greater than 90% woody cover (Celedonia 2002).

Competition and Non-Native Vegetation

The effect of competition on vegetation has been examined in several studies. The studies focused on specific species or treatments used to manage vegetation, factors that affect competition with non-native species, and the presence and extent of non-native species on compensatory wetland mitigation sites.

A few of the studies were conducted outside of the Pacific Northwest, and may have limited applicability to Washington State. For example, in the southeastern United States McLeod et al. (2001) determined that an existing willow canopy did not detrimentally affect the survival of three under-planted tree species. In the Midwest, Budelsky and Galatowitsch (2000) experimented with hairy sedge (*Carex lacustris*). The authors concluded, "*C. lacustris* can produce dense stands under a primarily annual weed community within two to three growing seasons, but that reed canary grass (*Phalaris arundinacea*) can preclude successful establishment of *C. lacustris*" (Budelsky and Galatowitsch 2000).

In the western Washington, Celedonia (2002) found that reed canary grass (*P. arundinacea*) can exist at relatively high densities (as much as 40% aerial cover) under

abundant canopy cover (>95%). This study was not able to determine: 1) whether reed canary grass was actually spreading through the understory, or whether it was a remnant, and woody species were establishing 'over' it; or 2) the extent to which reed canary grass inhibits establishment of desirable plant species during the re-initiation of the understory (Celedonia 2002).

Research has identified two factors that affect competition with non-native species.

- **Shrub density.** Celedonia (2002) observed, "greater shrub layer densities were associated with less reed canarygrass." The author suggests that an initial planting of a very dense shrub layer (e.g., more than 3,000 stems per acre) may help to preclude domination of reed canarygrass (*Phalaris arundinacea*).

- **Land use.** Magee et al. (1999) found that "the number of introduced and invasive/introduced species per site increases significantly with more intensive land use."

A few studies investigated how many compensation projects experienced problems with invasive species or how many non-native species occurred on sites. In Washington State, Johnson et al. (2002) noted that 61% of compensatory mitigation sites had at least 25% of the site dominated by non-native species. Celedonia (2002) found that nearly half of the sites visited in Washington had greater than 10% cover of reed canarygrass. In a study conducted by the Michigan Department of Environmental Quality (2000), "8% of mitigation sites were found to have a problem with invasive species" (defined as constituting 10% or more of the vegetation community).

In the Portland metropolitan area of Oregon, a study of vegetation at compensatory mitigation wetlands observed that non-natives composed more than half of the species present and "nine of the 14 most common taxa were invasive introduced species" (Magee et al. 1999).

Seed or Plant Source

The seed or plant source has been identified as important for restored wetlands (Reinartz and Warne 1993, Galatowitsch and van der Valk 1995). Restoration wetlands seeded with native wetland species had higher diversity and richness and less cover by cattails than the unseeded wetlands (Reinartz and Warne 1993). Emergent perennial species rapidly recolonized restoration wetlands possessing a viable refugium of wetland plant species (e.g., present in existing ditches) that spread through vegetative rooting (Galatowitsch and van der Valk 1995). The importance of proximity to a seed source was mentioned by Reinartz and Warne (1993) but discounted by Galatowitsch and van der Valk (1995).

Kellogg and Bridgham (2002), however, found that low density planting "offered no clear advantages over hydrologic restoration." Though seeding of a cover crop appeared to limit the establishment of aggressive species such as *Phalaris arundinacea*, it also appeared to limit establishment of wet prairie and sedge meadow species (Kellogg and Bridgham 2002).

Human Manipulation

A study conducted in the Willamette Valley of Oregon examined the response of wetland vegetation to three techniques for the restoration of wet prairie: burning, hand removal, and mowing (Clark and Wilson 2001). Results indicated that:

- **Burning** significantly reduced the survival and percent cover of woody species and non-native forbs (e.g., common St. John's-wort [*Hypericum perforatum*]), increased flowering of slender rush (*Juncus tenuis*), and increased cover of native forbs (e.g., Spanish-clover [*Lotus purshiana*] and marsh speedwell [*Veronica scutellata*]), but decreased flowering of tufted hairgrass (*Deschampsia cespitosa*), the dominant wetland prairie grass.

- **Hand removal** significantly reduced cover by woody species and non-native forbs, increased cover of native forbs, but increased flowering of non-native grasses (e.g., velvet grass [*Holcus lanatus*] and sweet vernal grass [*Anthoxanthum odoratum*]).

- **Mowing** had no effect on cover of woody species, but it increased the flowering of non-native grasses and significantly increased flowering of slender rush.

The authors concluded that though "no treatment was clearly superior in fulfilling the restoration objectives" mowing with removal of cut material was specifically not recommended (Clark and Wilson 2001).

6.8.3 Soil Characteristics

Soils are a critical component of wetlands. Soil characteristics can influence the growth and development of vegetation as well as the ability of wetlands to perform certain water quality functions. Researchers have investigated several factors related to wetland soil characteristics at compensatory wetland mitigation sites, including:

- Organic matter content
- Bulk density (compaction)
- Particle size
- Nitrogen content

Several authors used the approach of comparing soil conditions of created wetlands with reference wetlands. In these studies, the reference wetlands were either of the same wetland types as the mitigation wetlands, or they were adjacent to the mitigation wetlands. Only one study compared treatment plots to control plots at created wetlands. None of the articles on soil characteristics involved non-regulatory projects. Only one was conducted within the Pacific Northwest.

Results consistently indicated that the soil of created wetlands had a lower content of organic matter than reference wetlands (Brown 1991, Bishel-Machung et al. 1996, Streever et al. 1996, Shaffer and Ernst 1999, Whittecar and Daniels 1999, Stolt et al. 2000). Bishel-Machung et al. (1996) found that created wetlands had less organic matter than reference wetlands regardless of the Cowardin class or hydrogeomorphic class.

In the Portland metropolitan area, Shaffer and Ernst (1999) observed that both reference and mitigation wetlands with a high extent and duration of standing water had a lower concentration of soil organic matter. However, the authors also observed a consistent pattern of lower concentrations of organic matter in the soil of mitigation wetlands compared to reference wetlands within the same soil series, texture classes, and associations. Since many of the mitigation wetlands in this study involved construction of a pond in an existing wetland, the authors hypothesized that organic matter in mitigation wetlands is being lost due to the excavation of upper soil layers during project installation (Shafer and Ernst 1999).

In studies examining created wetlands from one to 11 years old and one to eight years old, the age of the created wetlands did not have an effect on organic matter content of the soil (Shaffer and Ernst 1999, Bishel-Machung et al. 1996). Concentrations of organic matter were relatively uniform between surface and subsurface samples. This indicated that accumulation of organic matter was either not occurring or was occurring so slowly it was not detectable (Bishel-Machung et al. 1996, Shaffer and Ernst 1999).

Stauffer and Brooks (1997) examined the effect of adding organic soil amendments to created wetlands. The authors found that plots treated with "salvaged marsh surface" (hydric topsoil) and leaf litter compost contained more organic matter than untreated, control plots. After two growing seasons, soil organic matter remained higher in plots treated with organic soil amendments.

Studies looking at particle size, bulk density, and nitrogen content found that soils in created wetlands had more sand, higher bulk densities (more compacted), and a lower nitrogen content than reference wetlands (Bishel-Machung et al. 1996, Whittecar and Daniels 1999, Stolt et al. 2000). In combination with low organic content, the soil characteristics of created wetlands may hinder plant establishment and growth (Whittecar and Daniels 1999, Stolt et al. 2000), denitrification and pollutant trapping (Stolt et al. 2000), and redox conditions (Bishel-Machung et al. 1996), thereby influencing microbial activity (Whittecar and Daniels 1999).

In contrast, Gilliam et al. (1999) found that redox levels and nitrogen content (in the form of ammonia) at an eight-month-old created wetland were comparable to a reference wetland after the created wetland was inundated. However, pH, phosphorus, manganese, magnesium, and zinc did not change noticeably at the created site. The authors concluded that eight months was "an insufficient period of time for a complete change toward hydromorphic soils."

6.8.4 Water Quality

Most of the water quality studies investigated the ability of created or restored wetlands to retain sediment, phosphorus, nitrogen, or some combination. One study compared water quality attributes at created and reference wetlands (Streever et al. 1996). None of the studies were conducted in the Pacific Northwest.

6.8.4.1 Comparison of Water Quality at Created and Reference Wetlands

Streever et al. (1996) determined that created wetlands had higher pH and conductivity than reference wetlands. The authors hypothesized that the amount of organic matter in the soil is related to pH and conductivity: "because decomposition of organic material releases CO2, lower pH values would be expected in natural systems with well-developed organic soils. A well-developed organic substrate may isolate surface water from underlying sand and rock, leading to decreased dissolution of minerals and lower conductivity." (See the previous discussion of soil characteristics in Section 6.8.3.)

6.8.4.2 Sediment Removal

Findings related to retention of sediment by created wetlands include the following:

- Wetlands created adjacent to roads were effective at retaining sediment, such that inflow culverts were clogged by accumulated sediment at a couple of sites (Moore et al. 1999).

- Mitsch (1992) found that a created wetland retained 90% of sediments, while a reference wetland retained 3%. The actual amount of sediment retained depends upon the loading rate.

- Fennessey et al. (1994) investigated the location within a created wetland where sediment was retained. Rates of sediment deposition, in general, were highest near the inflow and decreased as distance from the inflow increased, "except when outflow ceased, in which case the maximum sedimentation often occurred near the outfall." Open water areas also had higher sediment deposition than vegetated areas, which restricted flow. The authors observed that vegetation seems to present a barrier to water and sediment flow and, therefore, the study "did not illustrate the conventional belief that the presence of vegetation enhances sedimentation." The authors concluded, "deeper open water areas are more conducive to sediment accumulation than are shallower open water areas that are more easily subjected to wind-driven and biological sediment disturbances and subsequent re-suspension."

6.8.4.3 Nutrient Removal

In several studies, phosphorus retention at created or restored wetlands ranged from 16 to 96% (Mitsch 1992, Mitsch et al. 1995, Niswander and Mitsch 1995, White et al. 2000). In all but one of these studies, created/restored wetlands retained at least 53% of phosphorus (Mitsch 1992, Mitsch et al. 1995, White et al. 2000). The percent of retention varied depending on:

- Whether the wetland experienced high or low flows (Mitsch 1992, Mitsch et al. 1995)
- The configuration of the outflow
- The amount of time water was retained in the wetland (Niswander and Mitsch 1995)

White et al. (2000) mentioned that a restored wetland's capacity for phosphorus retention is limited. Sediments near the wetland inflow had a limited ability for additional uptake of phosphorus. However, approximately 66% of the marsh sediments still had a high capacity for uptake. The authors concluded, "future treatment efficacy may decrease if the remaining sediments become saturated. Continued high P [phosphorus] loading to the marsh may lead to eutrophication problems and downstream P export from the wetland."

Romero et al. (1999) found that total nitrogen retention was 30 to 91% at four restored wetlands. The authors attributed this to the high retention of dissolved inorganic nitrogen, while the retention efficiencies for particulate and dissolved organic nitrogen were much lower. The authors observed no significant difference between nitrogen retention and the age of the restored wetland.

Woltemade (2000) examined the factors that affect the ability of a created or restored wetland to retain nutrients. The most critical design elements for wetlands constructed to treat agricultural runoff were determined to be the retention time (amount of time that water is retained in the wetland) and the wetland-to-watershed ratio (size of the wetland compared to the size of its contributing basin):

> *If nutrient and sediment concentrations are to be reduced to acceptable levels on a landscape scale, drainage water must be retained for at least one to two weeks within wetlands before being discharged into streams. Monitoring of restored wetlands indicates that the longer the retention time, the greater the water quality benefits. . . Ultimately, the appropriate size of a restored wetland will depend on the contaminant of greatest local concern that requires the longest retention time for its degradation, and on the percent reduction of this contaminant that is required seasonally, annually, or interannually (van der Valk and Jolly 1992).* (Woltemade 2000).

6.8.5 Water Quantity

No studies were found that discussed the ability of created or restored wetlands to perform water quantity functions, such as decreasing downstream erosion or reducing peak flows, or that mentioned factors influencing a wetland's ability to perform water quantity functions.

Two studies compared the water regime of compensatory mitigation wetlands with reference wetlands. Both found that the compensatory wetlands had more standing water for a longer period (Shaffer et al. 1999, Cole and Brooks 2000).

6.8.5.1 Using Hydrogeomorphic (HGM) Classification to Study Water Regime at Mitigation Sites

Differences in the water regime between existing wetlands and mitigation wetlands have been examined by several researchers in the Pacific Northwest and elsewhere. The researchers used the hydrogeomorphic (HGM) classification to compare the water regimes of existing wetlands with those of mitigation wetlands. As described in Chapter 2, the HGM classification is based on the position of the wetland in the landscape (geomorphic setting), the wetland's water source, and the flow and fluctuation of the water once in the wetland. These are some of the major environmental factors that control wetland functions (National Research Council 1995).

Gwin et al. (1999) focused on HGM classifications of wetlands to determine how compensatory mitigation was affecting the wetland resource in and around Portland, Oregon. Classification of reference wetlands resulted in three regional HGM classes that were typical in the Portland metropolitan area: slope, riverine, and depressional. However, classification of mitigation wetlands

> *required development of new, atypical HGM classes to describe the unique combinations of site morphology and landscape setting found in these wetlands:*
>
> - *depression-in-riverine setting,*
> - *in-stream-depression, and*
> - *depression-in-slope setting* (Gwin et al. 1999).

Atypical refers to created or enhanced wetlands that do not match the geomorphic setting, water source, and/or hydroperiod found within the range of existing wetlands in a region. Gwin et al. (1999) characterized atypical classes by:

- Exaggerated depressional morphology with steep banks
- Large areas of open and/or deep water
- A large berm isolating the wetland from an adjacent stream channel
- Excavation within the stream channel producing an open water area wider and deeper than the original stream

In Washington 35% of compensatory mitigation projects resulted in wetlands of an atypical HGM class (Johnson et al. 2002). In Portland, Gwin et al. (1999) found that almost all of the enhanced wetlands and nearly half of the created wetlands resulted in an atypical HGM class.

What are the hydrologic consequences of creating atypical wetlands in the landscape? Shaffer et al. (1999) examined hydrologic conditions in reference and mitigation wetlands in the Portland metropolitan area. The study compared the regional HGM classes identified by Gwin et al. (1999)—slope, riverine, and depressional—with the atypical classes for mitigation wetlands—depression-in-riverine setting, depression-in-slope setting, and in-stream-depression. The results indicated significant differences. For example, slope wetlands had the lowest extent, depth, and duration of inundation, "while depression-in-slope wetlands had the highest water levels and greatest extent/duration of inundation" (Shaffer et al. 1999).

Similarly, Cole and Brooks (2000) noted that created wetlands were dominated by open water, while "most naturally occurring mainstem floodplain wetlands in central Pennsylvania are vegetated with very little open water." The authors concluded, "in the rush to make sure there is some water in mitigation wetlands we have gone too far in keeping sites inundated. In reality, many wetlands are merely saturated, or much drier" (Cole and Brooks 2000).

Schaffer et al. (1999) state:

> *Unless wetlands are restored or created in a manner that reproduces the hydrogeomorphic characteristics of naturally occurring wetlands in a region, management activities are unlikely to maintain or replace hydrologic and other valued functions of wetlands*.

Similarly, Cole and Brooks (2000) conclude:

> *The ecological consequences of a different hydrologic regime are clear. Standing water will promote anaerobic conditions in the soil, and the resulting soil chemistry will be defined by anaerobic pathways (Mitsch and Gosselink 1993). When combined with other common construction effects (e.g. soil compaction), this leads to difficult conditions for plant community establishment.*

In addition, water regimes exhibiting extensive areas of open water in mitigation wetlands hindered the formation of soil organic matter (Shaffer and Ernst 1999).

6.8.6 Summary of Key Points

- Functions performed and characteristics produced by created, restored and enhanced wetlands differed from those performed and produced by reference wetlands, except water quality functions, which appeared to be performed in a similar capacity.

- Most studies determined that reference wetlands provided habitat for a greater diversity or abundance of wildlife than created or restored wetlands. Birds were an exception since half of the studies found no difference between created/restored sites and reference wetlands, particularly for ducks.
- A variety of factors appeared to influence the abundance and diversity of wildlife at created or restored wetlands: development of vegetation communities, particularly emergent vegetation communities; age of the wetlands, which is often associated with the development of vegetation communities; and availability of a food source, often invertebrates, which is also often associated with the development of vegetation communities.
- Amphibian communities were affected by additional factors, such as the hydroperiod of the wetland, the presence of fish, distance to other wetlands, connectivity between terrestrial and wetland habitats, and surrounding land uses.
- Created and restored wetlands have different vegetation characteristics and plant communities than reference wetlands. A few studies found that certain plant communities, such as sedge meadows, may require many years to develop, if they develop at all.
- Compensatory mitigation is producing more acreage of open water wetlands than was lost. The ability of compensatory mitigation to produce other Cowardin classes varied.
- Several major factors were found to affect vegetation and plant communities, including the age of the wetland (older created/restored sites had a higher percent cover of emergent and woody species than younger sites); soil conditions (positive effects on vegetation resulted from adding hydric topsoil); competition (reed canarygrass can be problematic when attempting to establish emergent vegetation); and a source of native seeds or plants (this may speed up recolonization and increase diversity).
- Created, restored, and enhanced wetlands had less organic matter than reference wetlands. In addition, organic matter at compensation wetlands did not appear to accumulate over time. Plant establishment at compensation sites could be hindered by the low organic content in conjunction with soils that were found to be sandier, more compacted, and lower in nitrogen than soils at reference wetlands.
- Created and restored wetlands were comparable to reference wetlands at retaining sediments, phosphorus, and nitrogen. Factors affecting sediment and nutrient retention included the volume of water flowing into the wetland, the length of time water remains in the wetland, and the size of the wetland compared to the size of the basin.
- Some compensatory mitigation wetlands produced different HGM classes than were present in reference wetlands. This has resulted in wetlands that have more inundation for a longer duration than reference wetlands.

6.9 Reproducibility of Particular Wetland Types

This section discusses findings from the literature regarding the ability to restore, create, or enhance certain wetland types, such as bogs and fens, vernal pools, alkali wetlands, and mature forested wetlands.

6.9.1 Bogs and Fens

Bogs and fens are characterized by their highly organic soils, water regimes, and water chemistries. There were no studies of bog or fen restoration conducted in the Pacific Northwest. However, studies of bog and fen restoration in Northern Europe and Canada concluded that restoration may not be possible due to "irreversible changes of the biotic and abiotic properties" (Schouwenaars 1995, Schrautzer et al. 1996). This includes soil compaction and eutrophication (Grootjans and van Diggelen 1995, Schrautzer et al. 1996, Wind-Mulder and Vitt 2000) and other alterations to bogs resulting from drainage, peat harvesting, pollution, and agricultural practices (National Research Council 2001).

The studies mentioned difficulties in restoring bog vegetation communities (Bolscher 1995, Grosvernier et al. 1995, Schouwenaars 1995, Schrautzer et al. 1996), water regime (Grootjans and van Diggelen 1995, Schouwenaars 1995), and/or water chemistry (Wind-Mulder and Vitt 2000). Major conclusions include the following:

- Restore the water regime and the vegetation community will follow (Grootjans and van Diggelen 1995, Grosvernier et al. 1995).
- Prior to any restoration activity, the chemical state of the bog must be assessed. This influences the vegetation community and will, therefore, dictate the development of a restoration plan (Wind-Mulder and Vitt 2000).
- "Hydrological research may be crucial for a correct assessment of perspectives for rewetting" (Schouwenaars 1995). Prior to restoration it is necessary to determine the reason for a low water table because this affects the activities that will be required to restore a suitable water regime for the desired vegetation communities (Schouwenaars 1995).
- Bogs that were restored by rewetting and tree removal "differed from those of natural raised bogs, particularly in having taller and denser vegetation, a smaller range of moisture gradient and a more uniform vegetation physiognomy. Rewetted bogs did not have an undulating surface relief of hummocks and hollows" (Bolscher 1995).
- The best chance for restoration lies with restoring the least disturbed or damaged bogs or fens (Grootjans and van Diggelen 1995, Schrautzer et al. 1996).
- Restoration of bogs or fens will not yield rapid results (Grootjans and van Diggelen 1995).

- "Research has demonstrated that natural recovery of the moss surface following harvesting takes about 20 years (Elling and Knighton 1984)" (National Research Council 2001).

In terms of creation, research indicates that in reference systems organic soil (peat) accumulates at 0.1 to 3.8 mm per year (National Research Council 2001). At this rate it would take from 7 to 250 years for just 1 inch of peat to accumulate.

No information was available on the success or compliance of bogs or fens that were restored or created as wetland compensation. However, the literature suggests that bogs and fens cannot be reproduced within a regulatory timeframe.

6.9.2 Vernal Pools

Vernal pools are characterized by their short duration of inundation (National Research Council 2001). Thus, in order to reproduce a vernal pool, a site with a suitable substrate must be found and the correct depth and hydroperiod must be created or restored (National Research Council 2001). "In a long-term study of California vernal pools that were created by excavating depressions near natural pools, the hydroperiods did not converge with those of the reference systems until year 10 (Zedler et al. 1993)" (National Research Council 2001). If the hydroperiod is too long, the result will be an emergent marsh or an open water or aquatic bed system. If the site has inadequate substrate or is too shallow, the result may be upland with no inundation.

In terms of compliance, De Weese (1998) examined over 1,500 created vernal pools in California. She found that 83% of projects were in permit compliance, 96% met their hydrologic performance standards for depth of inundation, and 69% met vegetation performance standards. Seventy-two percent of projects were compared with reference vernal pools to determine their biological viability, while 35% of projects required some site remediation.

Guidance on construction has helped to transform the steep-sided "bathtubs" into pools that more closely mimic reference pools with gradual, vegetated slopes (De Weese 1998). De Weese (1998) concluded, "The art and science of constructing vernal pools have greatly improved over the past eight years [1987 to 1994]."

The literature suggests that, in California, vernal pools may be reproduced under the right conditions. However, the right conditions typically occur where vernal pools already exist, so creation of new pools merely increases the density of pools in an area (National Research Council 2001).

No information was found on the reproducibility of vernal pools in Washington.

6.9.3 Alkali Wetlands

No information was found that addressed the reproducibility of alkali wetlands.

6.9.4 Mature Forested Wetlands

Though studies have found that forested wetlands can be reproduced in Washington (Celedonia 2002, Johnson et al. 2002), *mature* forested wetlands have not been successfully reproduced simply because of the time necessary for the trees and the structural characteristics of the forest to mature (National Research Council 2001). Enhanced and created sites that have been planted often have a high density of stems to rapidly provide woody cover and shade out invasive species in the understory (Celedonia 2002, National Research Council 2001). Within a regulatory time-frame, compensatory mitigation wetlands may not begin to reproduce some of the attributes of mature forested reference wetlands unless these sites are thinned (National Research Council 2001).

6.9.5 Summary of Key Points

- The reproducibility of some wetland types is generally dependent upon time. For example, bogs, fens, and mature forested wetlands require several decades at a minimum, and possibly centuries, to develop the structural, chemical, biological, and hydrological attributes that characterize these wetland types.
- Studies suggest that vernal pools, at least in California, may be reproducible under the right conditions.

6.10 Suggestions from the Literature for Improving Compensatory Mitigation

A number of reports and articles suggested or recommended changes that could be made to help improve the effectiveness of compensatory wetland mitigation or alleviate problems that were frequently encountered. The recommendations described below are those of the authors of the literature sources cited, not the agencies or staff who have synthesized the information in this volume.

Data from a variety of sources are summarized throughout this section in a series of tables. To simplify the tables and efficiently use space, each literature source listed in the tables is represented by a reference number listed in Table 6-10. This is not a comprehensive list of all references cited in this section; see the references section at the end of Volume 1 for a complete list of literature sources.

Table 6-10. Literature sources and corresponding reference numbers.

18	Robb (2002)	36	Kellogg and Bridgham (2002)

The scientific literature contained recommendations that fall into three main categories:

- Recommendations for regulators of compensatory mitigation, including guidance on mitigation plans and monitoring reports, compliance tracking and enforcement, and alternative mitigation options
- Recommendations for site selection and design, including comprehensive wetland planning, baseline monitoring, hydrologic analysis, and considerations for site design
- Recommendations for implementing compensatory mitigation, including having a wetland biologist on-site to oversee construction activities, performing monitoring and maintenance of the site

The scientific literature provided more extensive information on additional topics:

- Performance standards
- Compensatory mitigation using a watershed approach
- Mitigation banking and in-lieu fees

Each of these is discussed below.

6.10.1 Regulatory Improvements

Of the suggestions provided by the scientific literature, the majority focused on elements that regulatory agencies should address (Table 6-11), such as:

- Improving guidance for every step of the mitigation process, from avoidance and minimization to submitting a monitoring report for a compensation wetland. This should help regulators with decision-making and provide applicants and consultants with more predictability
- Adjusting replacement ratios to reflect the risk of failure
- Requiring financial assurances or performance bonding
- Protecting all compensatory mitigation sites in perpetuity with a legal mechanism, such as a deed restriction or conservation easement
- Increasing regulatory follow-up and enforcement of compensatory mitigation projects, including developing and maintaining a database and filing system, allocating staff to perform compliance and enforcement activities, and implementing reviews of regulatory program performance
- Developing and implementing alternative mitigation options, such as advance mitigation, mitigation banking, and in-lieu fees

Table 6-11. Suggestions from the literature for regulatory improvement.

Suggestion	Reference No. [a]
Improve mitigation sequencing (i.e., avoidance and minimization)	5, 19, 29, 2, 10
Improve guidance for compensation projects, focusing on replacing functions as well as area	22, 29, 10
Improve site selection criteria. Site selection should be based on a watershed scale to maintain diversity, connectivity, and a balance of upland and wetland	5, 12, 15, 29, 2, 10
Improve goals, objectives, and performance standards, so that they are measurable, meaningful, achievable, and enforceable	13, 5, 31, 20, 19, 17, 9, 29, 10, 21
Standardize report format and elements for mitigation plans and monitoring reports, including an implementation schedule	13, 7, 8, 20, 17, 15, 2, 10

Suggestion	Reference No. [a]
Adjust (increase) replacement ratios to reflect the risk of failure. This should be based on the level of success of previous projects	1, 2, 18
Require performance bonding/financial assurances	13, 5, 8, 20, 15, 29, 2, 18
Require that compensation wetlands be protected in perpetuity with some kind of legal mechanism, such as a deed restriction or conservation easement	20, 29
Improve regulatory follow-up and enforcement of compensatory mitigation projects	5, 20, 19, 1, 30, 17, 15, 9, 29, 10, 18
Develop and maintain a permit/compensatory mitigation project tracking database and filing system	5, 7, 20, 19, 1, 17, 9, 15, 29, 2
Allocate staff for compliance and enforcement	5, 19, 17
Implement regular reviews of regulatory program performance	7, 19, 2
Implement studies of cumulative wetland loss (beyond what is recorded for regulatory permitting programs)	19, 1
Develop and implement alternative compensatory mitigation options: in-lieu fees, mitigation banking	20, 19, 1, 15, 29
Perform the compensatory mitigation in advance of the wetland loss	30, 29, 10, 18
[a] See Table 6-10 for a listing of literature sources that correspond to each reference number.	

6.10.2 Improving Site Selection and Design

The scientific literature also suggested site selection and design considerations (Table 6-12), including:

- Using a watershed approach to improve site selection
- Prioritizing wetland restoration
- Performing baseline monitoring of the wetland to be lost, identifying the wetland types and functions so that they can be replaced more effectively
- Performing baseline monitoring of the areas proposed for compensation to document the existing conditions and level of function
- Performing a hydrologic analysis for compensation wetlands to identify where the water will come from, how it will get to the site, and what the extent and duration of inundation or saturation will be
- Designing the compensation site to be self-sustaining and incorporating or simulating natural processes and structures, such as hydroperiods, slopes, shorelines, soils, topography, and vegetation

Table 6-12. Suggestions from the literature for improving site selection and design.

Suggestions	Reference No.[a]
Ensure that compensation wetlands will have a suitable source of water and compatible adjacent land uses	5, 28, 17, 29, 2, 10
Use a watershed approach to select compensation sites and support comprehensive wetland planning	19, 1, 28, 17, 29, 10
Prioritize restoration as the first choice for compensatory mitigation	17, 15, 29
Design compensatory mitigation wetlands to be self-sustaining and incorporate natural processes whenever possible	33, 29
Perform baseline monitoring of wetlands to be lost and areas proposed for compensatory wetland mitigation. Monitoring should characterize hydroperiod, soils, water quality, macroinvertebrates, and wetland functions	13, 5, 31, 20, 29, 10
Perform hydrologic analysis: identify hydrologic source, how water will get to the site, the intended depth and duration of inundation, and demonstrate that water source will be reliable and adequate Determine appropriate hydroperiod/hydrologic inputs early in the design stage, so that the water levels of the compensation wetland dictate how to design the building sites and roads, rather than letting the upland development create poor wetland conditions (too wet or too dry)	5, 31, 16, 28, 2
Grade slopes to be as gentle as possible; they should match the slopes of adjacent natural wetlands	6
Provide heterogeneous topography. For example, simulate microtopographic "mound and pool" features (e.g., wind-thrown or toppled trees)	23, 29
Incorporate native upland ecosystems into compensatory mitigation sites	5, 29
Deconsolidate (i.e., break-up) soils to reduce compaction and amend to insure adequate soil organic matter (e.g., 2 inches of coarse sand and 4 inches organic compost, natural hydric muck, or topsoil)	6, 16, 28, 32, 14
Take advantage of native seedbanks, natural recruitment, and salvaged topsoil and plants when available and feasible	29, 3, 4, 11
Minimize human encroachment by planting dense vegetation around the site or installing fences	26, 20, 16
Establish rapid canopy convergence and limit invasive species infestations by planting trees and shrubs at specific densities	25
Indicate the boundaries of the site with signs and markers	20, 16

[a] See Table 6-10 for a listing of literature sources that correspond to each reference number.

6.10.3 Improving Implementation

Compensatory wetland mitigation projects would be greatly improved if they were implemented as designed (Johnson et al. 2000, Balzano et al. 2002). The scientific literature provides numerous suggestions for improving implementation (Table 6-13), such as:

- Having a wetland biologist on-site during construction
- Monitoring the compensation wetland
- Develop an adaptive management plan that allows potential problems to be detected early and identifies how problems will be addressed
- Maintaining the compensation wetland to avoid problems and manage them early in the development of the site

Table 6-13. Suggestions from the literature for improving implementation.

Suggestion	Reference No.[a]
Wetland biologist on-site to oversee construction or train/educate contractors and to authorize and document any necessary changes	5, 31, 9, 2
Monitoring of mitigation sites should characterize baseline, construction, as-built, and post-construction conditions. Monitoring reports should include a section on lessons learned	13, 6, 5, 24, 7, 31, 8, 20, 19, 15, 9, 2, 10
Monitoring parameters and methods should be specific to a project's goals, objectives, and should include: project size, shape, topography, hydroperiod, water quality, flora, and fauna	5, 17, 33
Monitor compensatory mitigation wetlands. Duration of monitoring may range from 3 to more than 20 years, depending on the size of compensation wetland, the proposed wetland type (e.g., Cowardin class), and the likelihood of success	5, 34, 35, 17, 15, 10, 29, 36
Monitor hydrology during the first growing season to characterize the site's hydroperiod. Develop and implement a planting plan after the hydroperiod has been characterized	27
Perform long-term monitoring after a project has been deemed successful to keep track of it over time, study how it matures, use it as model for other sites	5, 28, 36
Develop an adaptive management program, which includes early monitoring of wetland structure, processes, and functions to detect potential problems and allow for corrective actions	29
Maintain compensatory mitigation sites, including a contingency plan for how to address problems. Maintenance should focus on controlling invasive species, providing irrigation, replacing dead plants, correcting slopes and topography	13, 24, 31, 8, 2, 10, 29
[a] See Table 6-10 for a listing of literature sources that correspond to each reference number.	

6.10.4 Performance Standards

Performance standards, performance criteria, success criteria, success measures, standards of success, and other terms all refer to regulatory conditions used to determine how effective a mitigation project is at meeting regulatory requirements, which may or may not include compensating for wetland loss. Ideally performance standards should serve as "measurable benchmarks used to evaluate the development of ecological characteristics associated with specific wetland functions" (Azous et al. 1998). Performance standards allow regulators to determine if a compensatory mitigation project has fulfilled its goals, and also provide a mechanism for regulators to implement enforcement actions against unsuccessful projects (Streever 1999).

As explained in Chapter 2, wetlands differ in how they function, by geomorphology and water regime and other characteristics. Compensatory wetland mitigation projects, likewise, exhibit considerable variability with different types of wetland compensation (creation, restoration, etc.). The variability makes it difficult to develop and require universal performance standards, yet in the absence of some kind of uniformity, performance standards that are approved can lack meaning.

6.10.4.1 Shortcomings of Existing Performance Standards

Sheldon and Dole (1992) performed a study of eight compensatory mitigation projects in King and Snohomish Counties in Washington. The authors observed that "none of the goal statements provided a quantifiable method of determining success, thus they provided no means for an agency to assess success/failure or to require remediation." The Michigan Department of Environmental Quality (2000) similarly found, "The practice of including no specific performance standards, or only very general performance standards (regarding the size and possibly the type of wetland to be constructed), resulted in many unenforceable permits and contributed to the poor quality mitigation wetlands."

Johnson et al. (2000), in their study of 45 compensatory mitigation wetlands, noted some problems with performance standards, such as:

- Standards that are too general or "easy to attain" and, therefore, are not indicative of ecological development at a site
- Standards that are not measurable and, therefore, cannot be used to evaluate the success or compliance of projects
- Standards that contain confusing or ambiguous language and, therefore, result in inaccurate assessment or preclude assessment

In addition, Johnson et al. (2002) in their evaluation of 24 compensation projects excluded performance standards that were unrealistic, not feasible, or so rigorous that the standard may never be attained. Such standards were ". . .setting sites up for failure" and therefore ". . .did not reflect how the site was functioning or progressing ecologically"

(Johnson et al. 2002). Ossinger (1999), in a guidance document for the Washington State Department of Transportation, suggests that performance standards should strike a balance between accountability and flexibility. The author recommends that crafting performance standards requires a technical knowledge of the quantitative values that are achievable, or to be expected, for the wetland attributes targeted by the standard.

Approved mitigation projects can also lack performance standards for important wetland functions or conditions. Breaux and Serefiddin (1999) discovered in their review of 110 projects in San Francisco, California, that only 22% had quantitative standards focusing on hydrological parameters. Johnson et al. (2000) reviewed 179 performance standards from 36 projects and observed that 8% of the performance standards related to hydrological conditions. The Michigan Department of Environmental Quality (2000) found that "none of the permits examined contained any specific criteria regarding vegetation or hydrology by which the mitigation wetland could be judged for success or failure." Johnson et al. (2002) noted that most of the projects evaluated in their study of 24 compensation wetlands lacked basic standards for wetland area, water regime, area of Cowardin classes, percent cover of native wetland vegetation, and maximum percent cover of invasive vegetation.

Breaux and Serefiddin (1999) argue, "In seasonal wetlands, hydrology clearly ought to be the reigning criterion given that the successive presence and absence of water is the defining characteristic of a seasonal wetland." However, the authors go on to admit, "there is no agreement as to what the specific hydrological criterion should be."

6.10.4.2 Use of Reference Wetlands in Developing Performance Standards

Brinson and Rheinhardt (1996) state that "the proper use of reference wetlands removes potential bias and provides the foundation for more objective functional-assessment procedures…reference wetlands should be central to the development of standards against which impacts to wetlands and restoration efforts are evaluated."

Azous et al. (1998) also support the use of reference wetlands:

> *By collecting data on the ecological characteristics associated with reference wetlands, and created or restored wetlands, standards of comparison can be established by which to judge the development of wetland characteristics in compensatory mitigation projects. The use of regional reference wetland characteristics provide greater assurance that project performance standards will be reasonable (i.e., attainable) and useful gauges of the development of wetland functions.*

For example, a compensation wetland might have a goal to provide amphibian habitat by the end of the monitoring period. Based on an evaluation of 24 depressional, flow-through, reference wetlands in the Puget Lowlands of western Washington, Azous et al. (1998) proposed performance standards to determine if amphibian habitat had successfully been established. "The standards include specific guidelines for planning

and designing mitigation projects to provide preference for the establishment of amphibian breeding, feeding, and refuge habitats." The authors suggested the following standard, "Wetlands created for amphibian habitat should have thin-stemmed emergent plants that comprise at least 30% or more of the total wetland area (Azous et al. 1998)."

However, Whittecar and Daniels (1999) mention a problem with using reference wetlands to develop benchmarks or performance standards for compensatory mitigation:

> *[U]nlike the mitigation site, reference wetlands coexist with landforms that may have required thousands of years to form (Brinson et al. 1995). Each wetland has a history that influences modern functions. Many of these functions will not redevelop in the new wetland within a time span acceptable to regulatory constraints without thoughtful planning and careful attention to construction.*

Ehrenfeld (2000) recommends that reference sites be identified in urban areas and used to develop attainable performance standards for compensatory wetland mitigation projects that are also located in urban areas. The author states: "Measures of restoration success and functional performance must start with an appreciation and assessment of the particular conditions imposed by the urban environment."

6.10.4.3 Longer Period Needed to Evaluate Projects

Part of the problem with developing achievable performance standards is that monitoring periods or regulatory timeframes for the majority of compensatory mitigation projects are relatively short (five to 10 years). The "success" or compliance of compensatory mitigation projects is, therefore, determined or evaluated when the site is still relatively young and immature (Kentula 1995, Mitsch and Wilson 1996). Longer monitoring periods are necessary to allow for secondary succession and natural events (e.g., drought or floods) that may affect or restructure vegetation communities (Kellogg and Bridgham 2002). Long term monitoring would also result in larger data sets upon which realistic performance standards and project goals could be based (Kellogg and Bridgham 2002).

If projects are to be evaluated within five to 20 years, then they should be compared to other compensatory mitigation projects. Kentula (1995) suggests comparing "wetland creation and restoration projects to each other and to similar, naturally occurring wetlands to define standards for project performance over time." She describes an approach for developing performance standards based on monitoring information from previous projects. "In this way, we can be assured that new projects are doing at least as well as past projects."

Celedonia (2002) implemented Kentula's approach by conducting a study of 29 compensatory mitigation projects from six to 11 years old in the lowland wetlands of western Washington. Time series curves were created from the data to determine at what point in time projects could be expected to meet certain vegetative standards, such as percent areal cover of woody vegetation. Based on the data, the author proposed that by year eight a mitigation site could attain 80% cover of native woody vegetation.

6.10.5 Compensatory Mitigation Using a Watershed/Landscape Approach

In the context of compensatory mitigation, a watershed approach means:

> *to recognize that management of wetland types, functions, and locations requires structured consideration of watershed needs and how wetland types and location serve these needs. A watershed approach means that mitigation decisions are made with a regional perspective, involve multiple agencies, citizens, scientists, and nonprofit organizations, and draw upon multiple funding sources (e.g., permittee-responsible, mitigation banks, and in-lieu fees). A watershed approach means that permitting decisions are integrated with other regulatory programs (e.g., storm water management or habitat conservation) and nonregulatory programs (e.g., conservation easement programs)* (National Research Council 2001).

Bedford (1996) explained the need for a watershed/landscape approach as follows:

> *From a policy perspective, the central issue in wetland mitigation is not the effects on a single site but the cumulative effect of numerous mitigation decisions on landscapes. Mitigation must be recognized as a policy that has the potential to re-configure the kinds and spatial distribution of wetland ecosystems over large geographic areas. … The net effect is the loss of wetland diversity in terms of both hydrologic functions and biological communities, and a consequent homogenization of wetland landscapes. One way to avoid such cumulative effects is to make decisions about individual projects within a framework focused at larger scales (Lee and Gosselink 1988).*

This section describes recommendations from the literature for methods to implement a landscape or watershed-scale approach in order to improve the success of mitigation projects. Further discussion of restoration using a landscape approach is included in Chapter 7 in the context of addressing cumulative impacts to wetlands.

6.10.5.1 Methods for Implementing a Landscape Approach

Three types of watershed planning are described in a report by the National Research Council (2001):

- **Management-oriented** wetland planning, which would replace case-by-case permitting. Decisions about permitting, mitigation sequencing, and the acreage, type, and location of compensation would be made in advance using a watershed approach. This type of watershed plan would require regulatory and non-regulatory programs to be coordinated.

- **Protection-oriented** wetland planning, which is focused on avoiding wetland loss and alteration by identifying wetlands and their ecological value. This type of watershed plan would be used during the mitigation sequencing process.

- **Compensation** wetland planning, which "identifies watershed needs for types, functions, and general locations of wetlands in the landscape in order to establish restoration priorities for both regulatory and nonregulatory programs. …This type of planning might link projects undertaken through both regulatory and nonregulatory programs to secure some desired mosaic of wetlands in the landscape."

Hashisaki (1996) discusses the utility of a landscape-level analysis to examine conditions not just at an impact, compensation, or reference site, but also in the surrounding landscape. A landscape-level analysis "considers the effect of historic, current, and proposed land management practices on the individual functional indicators. . . . In addition to identifying constraints on land management practices, it can be useful in identifying critical preservation and restoration opportunities. Understanding the control that human activities exert on the disturbance regimes of an ecosystem allows projections about expected future conditions."

Bedford (1996) recommends developing wetland profiles/templates based on the diversity of wetland types that exist in a region as a result of the unique interaction of hydrogeology and climate. By understanding the current and historic wetland types and their relative abundances in a region, decisions regarding compensatory mitigation can be made to help maintain the diversity and hydrologic equivalence.

In some cases, using a watershed approach may result in a watershed plan that identifies all the wetlands in an area and assesses the functions that they perform. Hruby and Scuderi (1995) used this approach for a watershed near Seattle, Washington, that was experiencing development pressure. The goal of the plan was "to ensure that the performance of wetland functions and their societal values continue to be equal to or greater than those currently existing…" (Hruby and Scuderi 1995). Wetland areas targeted for restoration or enhancement were assessed to quantify how much wetland function could be gained. The proposed/potential gain in function through restoration/enhancement could then be used to determine how much wetland function could be lost to development activities in the watershed.

A report by the National Research Council (2001) proposed that "Functional tradeoffs might be considered in the context of the needs of the watershed." A watershed plan would be developed for an area, such that the functions of wetlands proposed for loss or alteration are understood, as well as the needs of the watershed for wetland functions. Functions that are abundant or a low priority in a watershed could be lost and replaced by other functions that are limited or a higher priority in the watershed.

Race and Fonseca (1996) point out that on a national level, a landscape approach to land use and compensation would require the cooperation/participation of thousands or millions of private landowners:

> *Taking a large-scale, ecosystem approach to wetlands management is a significant change in natural resource management policies, one representing a major paradigm shift that will require radical revision in values, management practices, and institutional structures in order to succeed (Cortner and Moote 1994). …Thus, integrating ecologically relevant concepts such as landscape-scale decision criteria need more than good science; it will also require conscious redesign of the entire permitting infrastructure to avoid legal challenges.*

6.10.6 Mitigation Banking

Compensatory mitigation banking and other third-party compensation approaches (in-lieu fee, market-based mitigation) are believed by some to provide part of a solution and have offered new hope for successful compensation of wetland impacts (Kukoy and Canter 1995).

Currently, even when wetlands have been avoided or established as compensation they often "have diminished ecological functions from polluted runoff, from changes in hydrologic regimes, and from the fragmentation of the landscape which isolates the wetlands from the surrounding uplands, water, and biological resources of the watershed" (Shabman et al. 1993).

In addition, some federal, state, and local permits for wetland loss do not require compensatory mitigation because the individual impact is so small that compensation is considered impractical, despite the fact that cumulative losses are occurring (Shabman et al. 1993, Kukoy and Canter 1995, Weems and Canter 1995). Finally, even when compensatory mitigation is required there is no guarantee that it will be implemented or successful.

Shabman et al. (1993) outlined a market solution to improve compensatory wetland mitigation. Market-based mitigation approaches start with an entrepreneurial restoration firm seeking to make a profit from selling a product—a wetland ecosystem. If the product is not of a particular quality then it will not sell. For example, if the wetland bank is not in compliance, not meeting its performance standards, or not providing the proposed functions then the regulatory agencies will not accept credits from the bank as compensation for wetland losses. The permit applicant, therefore, will not purchase the "product" of the wetland bank. This is the incentive for the restoration firm to establish a functioning wetland ecosystem.

In addition, a restoration firm can take the time to find a suitable location for the wetland that will minimize problems with fragmentation (Kukoy and Canter 1995). Wetland banks can also secure large sites for restoration that would not be feasible on a small project scale (Weems and Canter 1995).

Once the wetland is established, credits or tradable portions of the wetland can be made available for purchase to compensate for wetland losses (Weems and Canter 1995), even wetland losses that were previously too small to require compensation (Kukoy and Canter 1995). It is assumed that the availability of bank credits for compensation can also provide efficient permitting since the applicant would not have to worry about getting a mitigation plan approved, and regulators could more readily assess the effectiveness of the compensation.

Mitigation banking in Washington State has been more thoroughly discussed in the *Draft Programmatic Environmental Impact Statement: Washington State's Draft Rule on Wetland Mitigation Banking* (Driscoll and Granger 2001, available at: http://www.ecy.wa.gov/biblio/0106022.html). For additional information on mitigation banking and in-lieu fee programs refer to *Banks and Fees: The Status of Off-Site Wetland Mitigation in the United States* (Environmental Law Institute 2002).

6.10.7 Summary of Key Points

- The scientific literature provided suggestions for improving virtually every aspect of the mitigation process from regulatory guidance and policies to specifications for controlling invasive vegetation.
- Suggestions included measurable, meaningful, achievable, and enforceable performance standards; better sites that provide increased benefits due to their location within a watershed; better monitoring of compensatory mitigation wetlands; and measures to increase regulatory follow-up of compensation projects.

6.11 Chapter Summary and Conclusions

Wetland compensatory mitigation has been studied in Washington and elsewhere in the United States for the past 15 years. Considerable data are available to evaluate the effectiveness of compensatory mitigation.

The majority of compensatory wetland mitigation projects described in the literature was neither fully successful nor completely unsuccessful. Most projects were found to have an intermediate level of success. While most compensatory mitigation projects were installed, compliance of the projects with permit requirements was generally low. The authors of Volume 1 hypothesized that this was due to shortfalls of wetland acreage, failure to achieve performance standards, and a lack of monitoring and maintenance. The few studies that examined the effect of regulatory follow-up suggested that it had a positive influence on the level of compliance and success for compensatory wetland mitigation projects.

There is a general lack of information about the relative effectiveness of the various types of compensation (e.g., restoration, creation, enhancement, etc.). Creation is generally the most frequently used type of compensation, but studies of its effectiveness produced

mixed results. Enhancement of wetlands was also frequently used, but few studies examined its effectiveness. Limited studies from Washington indicated a low level of success among enhanced wetlands, primarily due to a minimal gain in functions. Restoring wetlands was noted as a high priority, but as a type of compensation it is not frequently used.

Preservation and a mixture of compensation types appear to be used occasionally. Studies provided limited information on the effectiveness of these types. Two studies from Washington indicated that mixed compensation projects had a higher level of compliance than creation or enhancement, and all mixed projects were moderately successful. The lack of data regarding the effectiveness of preservation is problematic since one of the only studies to look at its effectiveness determined that one large site was predominantly upland habitat. On the other hand, if a site can be confirmed as wetland, or if a mosaic of wetland and upland is determined to be acceptable, preservation of existing wetlands offers no risk of failure and no temporal loss of wetland functions, which are inherent in the other types of compensation. Preservation does, however, result in a net loss of wetland area and possibly functions.

Replacement ratios attempt to equalize the trade-off between the wetland being lost and the wetland being provided as compensation by accounting for the risk of failure and temporal loss of functions. Required replacement ratios vary from one state to another, based on the type of compensation proposed, and based on project-specific circumstances. Replacement ratios actually achieved through compensation were less than what was required, which is to be expected since the ratios are meant to encompass a certain level of failure. However, in some cases this resulted in less than 1:1 acreage replacement.

Studies relying solely on permit files and databases indicated that permitting programs have improved over time in terms of wetland acreage required for compensation. However, studies which relied on site visits and field analyses indicated that compensatory wetland mitigation has resulted in a loss of wetland acreage.

Functions performed and characteristics produced by created and restored wetlands differed from those performed and produced by reference wetlands, except water quality functions, which appeared to be performed in a similar capacity. None of the studies compared the functions provided by compensation wetlands with the functions provided by the wetlands that were lost.

For the most part, reference wetlands provided habitat for a greater diversity or abundance of wildlife than created or restored wetlands. Birds were an exception since half of the studies found no difference between created/restored sites and reference wetlands, particularly for ducks. Created and restored wetlands have different vegetative characteristics and plant communities than reference wetlands. Certain plant communities, such as sedge meadows, may require many years to develop if at all.

The authors of Volume 1 conclude that the common finding that wetland compensation sites have greater vegetation species richness is linked to the broad range of niches created on a new site. A newly created or restored site is a “blank slate” upon which

species will be planted, species from the previous habitat on the site will re-emerge, and species adapted to disturbance will colonize. Over time the site will stabilize and mature and only the species adapted to the resulting conditions will remain. However, research on restored, created, or enhanced sites that have stabilized is currently lacking. One could infer, therefore, that sites are not studied for a long enough time, due either to the relatively short regulatory timeframe or the decades or lifetimes necessary to achieve stabilization and maturity.

Researchers observed that created, restored, and enhanced wetlands had less organic matter than reference wetlands. This could be due to the excavation of surface soil layers during project construction. Studies also indicated that organic matter at compensation wetlands did not appear to accumulate over time. Therefore, plant establishment at compensation wetlands could be hindered by low organic content in conjunction with soils that were found to be sandier, more compacted, and lower in nitrogen.

Compensatory mitigation is producing more acreage of open water wetlands than was lost. The ability of compensatory mitigation projects to produce other Cowardin classes varied. Some compensatory mitigation wetlands have produced different HGM classes than were present in the reference wetlands. This has resulted in wetlands that have more inundation for a longer period than reference systems.

Some unique types of wetlands, such as bogs, fens, and mature forested wetlands, may not be reproducible, especially not within current regulatory timeframes. Other wetland types, such as vernal pools, may be reproducible given the right conditions.

The literature provided numerous suggestions on virtually every aspect of the mitigation process. Key suggestions include:

- Improving regulatory guidance on a variety of topics, such as measurable, meaningful, achievable, and enforceable performance standards for compensatory mitigation
- Finding better sites that provide increased benefits due to their location within a watershed
- Monitoring compensatory mitigation wetlands more effectively
- Implementing measures to increase regulatory follow-up of compensation projects

The literature suggests that some improvements have been made in compensatory mitigation over the past two decades, particularly in terms of what is required. However, overall success and permit compliance have not noticeably improved. Most studies indicate that created and restored wetlands do not provide the same characteristics or level of functions as reference wetlands (water quality functions may be the exception).

Since the effectiveness of compensatory mitigation remains highly variable and somewhat questionable, it is increasingly important to understand the cumulative effects of the continuing loss of wetland acreage and functions. This will be addressed in the next chapter.

Chapter 7

Cumulative Impacts to Wetlands and the Need for a New Approach

"Evidence in increasing that the most devastating environmental effects may result, not from the direct effects of a particular action, but from the combination of individually minor effects of multiple actions over time." (Council of Environmental Quality 1997)

7.1 Reader's Guide to This Chapter

This chapter introduces the concept of "cumulative impacts" to represent the incremental losses and degradation of wetlands that continue in spite of all the existing regulatory and non-regulatory actions we are taking to protect them. The chapter discusses different types of cumulative impacts and the loss of wetland area as the most easily assessed measure of cumulative impacts. It goes on to present some of the causes of cumulative impacts in Washington.

The synthesis of the scientific literature in Chapters 2, 3, and 4 has clearly established that wetlands do not function in isolation from the landscape that surrounds them. A wetland's ability to provide certain functions is influenced by the conditions and land uses within their contributing basins, especially by the patterns of water flow and movement that can be changed by different land uses. Existing wetland regulations usually are structured so decisions are made on an application by application basis. There are no provisions for assessing or considering the implications of individual decisions on the resource in general. The information presented in previous chapters demonstrates that project-by-project decisions cannot adequately address the complexities of wetland systems, and new approaches are needed to reduce the continued impacts to wetlands.

7.1.1 Chapter Contents

Major sections of this chapter and the topics they cover include:

Section 7.2, Loss of Wetlands as an Indicator of Cumulative Impacts describes the total wetland losses in Washington and three studies in the Pacific Northwest that illustrate more recent loss.

Section 7.3, Types of Cumulative Impacts describes how cumulative impacts result from disturbances related to geography and time that are not adequately managed. It lists types of cumulative impacts such as fragmentation and time lags.

Sections 7.4, Causes of Cumulative Impacts in Washington describes how the current approach to wetland management and protection results in cumulative impacts. The causes discussed include case-by-case permitting, lack of consistency between jurisdictions, and implementation of local programs for protecting wetlands through regulations. Different types of cumulative impacts are listed along with examples of possible causes from inadequate protection at the local level.

Section 7.5, Chapter Summary and Conclusions ties together the major concepts presented in the chapter.

7.1.2 Where to Find Summary Information and Conclusions

One summary is provided at the end of the chapter, along with the authors' conclusions. The reader is encouraged to remember that a review of the entire section preceding the summary is necessary for an in-depth understanding of the topic.

7.1.3 Sources and Gaps in Information

Much of the literature published on the topic of cumulative impacts is not specific to wetlands. Most of the research has been focused on environmental processes that affect biodiversity (i.e., habitat loss, fragmentation, metapopulations). The available information is weighted toward the impacts of some types of land use (urbanization and forest practices), with less information available on the impacts from other types of land use (agricultural practices, mining).

The 1997 Council of Environmental Quality report (Executive Office of the President) is a key document on cumulative impacts in general, and it provides a good summary of how land uses can cause cumulative impacts. This document is available on the internet at: http://ceq.eh.doe.gov/nepa/ccenepa/ccenepa.htm . This information can be applied to the protection and management of wetlands in the state.

The information available that specifically addresses wetlands is very general in nature and addresses cumulative impacts to wetlands only in terms of direct loss of wetland area, not the changes in functions that might result from changes in environmental processes at the landscape scale.

There is a significant gap in information regarding the cumulative impacts to wetlands and their functions resulting from the current approaches to managing wetlands at any level of government. The gap regarding the cumulative impacts and local protection programs is especially significant. The legal framework within Washington State (see Chapter 2 in Volume 2), delegates the decisions about land use, including comprehensive planning, designation of zoning, and regulation of critical areas, to local governments. As the information synthesized in Chapters 2-4 of this document has shown, decisions that change land uses can cause impacts to wetlands. However, little research has been conducted on the effectiveness of local efforts in effectively planning for and protecting wetlands, thereby preventing cumulative impacts. Only two studies were found that

review the effectiveness of local protection programs for wetlands, and they dealt with specific topics relating to regulations: standards for compensatory mitigation in King County and buffer requirements in the critical area ordinances of local jurisdictions in Washington in 1999 (See section 7.4.3).

Some hypotheses about the effectiveness of local programs, however, can be made by correlating the findings of the relevant literature with different aspects of the regulatory framework for wetlands used by local governments. The scientific information provides ample guidance on what is needed to protect wetland functions (e.g., planning to address and protect landscape processes, providing adequate buffers, modifying current practices of compensatory mitigation). A comparison of this information to the usual standards found in current programs can provide insights about the effectiveness of these programs. If they do not provide the range of measures for protection that are suggested by the scientific literature, it can be hypothesized that those programs may not be providing adequate protection to prevent cumulative impacts and assure long-term sustainability of wetlands.

What are Cumulative Impacts?

Cumulative impact, as defined by the Council on Environmental Quality, "is the impact on the environment which results from the incremental impact of the action when added to other past, present, and reasonably foreseeable future actions regardless of what agency (Federal or non-Federal) or person undertakes such other actions. Cumulative impacts can result from individually minor but collectively significant actions taking place over a period of time." http://ceq.eh.doe.gov/nepa/regs/ceq/1508.htm#1508.1

Cumulative impacts also have been described by Hemond and Benoit (1988) as follows: "Wetlands are frequently subject to multiple impacts over time and/or space; the effects of such multiple impacts may be simply additive, or the total effect may be more severe than the sum of the effects of the individual impacts alone. Cumulative impact as used here refers to multiple impacts whose effects on the wetland cannot be predicted by simply adding the effects of all the individual impacts."

7.2 Loss of Wetlands as an Indicator of Cumulative Impacts

The loss of wetland area that continues to occur as a result of human activities is a general indicator that cumulative impacts are occurring. A net loss of wetland area and the functions it supports is a measure of the incremental impacts of human activities that are not adequately addressed. At the national level, wetlands continue to be lost, according to a report released by the National Research Council (1995). The U.S. Environmental Protection Agency states that although wetland loss rates are slowing, the United States continues to lose approximately 70,000 to 90,000 acres (28,300 to 36,400 ha) of wetlands on non-federal, rural lands each year (U.S. Environmental Protection Agency 2002).

Here in Washington, the state has lost an estimated 31% of its 1.35 million acres (55 million ha) of wetlands up to the 1980s (Dahl 1990). Recent data on total wetland losses in the state are not available, but three studies in the Pacific Northwest illustrate that the loss of wetlands continues:

- Bell (2002) studied sphagnum-dominated peatlands that were originally mapped by Rigg in the early 1950s in King County. Bell found a 69% loss of these wetlands since 1958. Of 26 sites, six remained relatively undisturbed. Eight showed a decline in acreage and quality of plant communities. Five wetlands are now highly disturbed with no sphagnum moss present. The remaining seven wetlands were either drained or filled. Of the 406 acres (162 ha) present in 1958, only 125 acres (50 ha) remain today. The losses were due to agricultural conversion, development, and peat mining.
- A study of recent losses of wetlands within the Willamette Valley, Oregon, found that from 1981/1982 to 1994 there was a loss of approximately 9,500 acres (3,800 ha) of wetlands, representing approximately a 2.1% loss of wetlands within the Willamette Valley study area. They found that 70% of the loss was attributable to agriculture, 6% was associated with the impacts of urbanization, and 24% was attributable to other unidentified causes (Bernert et al. 1999).
- A study conducted by Holland et al. (1995) in the greater Portland, Oregon, area found that 40% of the wetlands identified in the National Wetland Inventory of 1981/1982 were missing in 1992. They attributed most of the loss to the impacts of urbanization, yet they still attributed 31% of the losses to agricultural conversion. One conclusion of their study was that small, often isolated wetlands were lost due to decisions regarding single-project permits that did not take into account the overall pattern of wetland loss.

In addition to the direct loss of wetlands, alterations have occurred from human activities such as diking, draining, and agricultural practices (Washington State Department of Natural Resources 1998). These changes, even if apparently small on an individual basis, can have a cumulative impact on the functions of wetlands.

7.3 Types of Cumulative Impacts

Cumulative impacts result from the spatial (geographic) and temporal (time) crowding of disturbances that are not adequately managed. The impacts of a disturbance can be compounded when a second disturbance occurs at a site before the ecosystem can fully recover from the effect of the first disturbance (Council of Environmental Quality 1997). The scientific community has not yet agreed on a standard definition or method for assessing cumulative impacts because of the diversity of disturbances, the complexity of environmental processes, and the diversity of impacts possible (Council of Environmental Quality 1997). Nonetheless, the Council was able to identify eight scenarios (types of cumulative impacts) by which cumulative impacts occur (Table 7-1). These types are discussed further in Section 7.4.4 (Table 2) in relation to various causes of cumulative impacts in Washington.

Table 7-1. Types of cumulative impacts (modified from Council of Environmental Quality 1997)

Type of Cumulative Impact	Main Characteristics	Examples of Cumulative Impacts
Time crowding	Frequent and repetitive disturbances before the ecosystem has recovered from previous disturbance	Changes in the water regime that increase the depths of water and duration of flooding that, in turn, drowns vegetation not tolerant to prolonged inundation
Time lags	Impacts of disturbance are delayed from the time the disturbance occurs	Changes in water regime that causes a slow shift in the vegetation to species not suitable as sites for laying amphibian eggs
Space crowding	Impacts are occurring in close physical proximity to each other	Construction of new roads and commercial land uses on opposite sides of a wetland, resulting in increased human disturbances, such as noise, lighting, and less upland habitat
Cross-boundary	Impacts occur away from the source	Eutrophication in wetlands and lakes that results from discharges of nutrients in upper watershed
Fragmentation	Changes in the pattern of ecosystems across the landscape	Construction of a subdivision with roads interrupts the natural pathways used by animals for movement between patches of habitat
Compounding effects	Impacts arising from multiple sources or pathways	A small buffer reduces the upland habitat needed for wildlife that is closely associated with wetlands and that allows intrusion by humans and domestic pets
Indirect effects	Additional disturbances that result from changes in human activities that themselves are a result of the initial disturbance	The additional impacts that result from development after roads or other infrastructure are built. The building of a road has direct impacts but also changes human activities that cause additional ones.
Thresholds and triggers	The accumulation of disturbances causes a fundamental change in the behavior of the ecosystem	Changes in land use result in increased surface runoff that causes streams to become incised. As a result, wetlands become disconnected from the floodplain.

7.4 Causes of Cumulative Impacts in Washington

Some of the causes of cumulative impacts on wetlands stem from how wetlands are regulated in Washington State, and how local governments plan for future land use and development. Local city or county governments generally have the authority to plan for, manage, and otherwise regulate land uses within their jurisdictional boundaries, including those within and adjacent to wetlands. They may regulate what occurs directly in a wetland and, in many cases, they regulate land uses adjacent to a wetland and its buffer (see Volume 2). Federal and state agencies may regulate many direct impacts to wetlands. However, state and federal agencies do not regulate all activities that take place in wetlands and do not regulate land uses in the uplands around a wetland. They also don't provide the comprehensive planning and inter-jurisdictional coordination that affects cumulative impacts. Thus, federal and state agencies that regulate wetlands do not manage, and cannot protect, all wetlands nor many of the landscape processes that influence the functions that wetlands provide.

7.4.1 Case-by-case Permitting as a Cause of Cumulative Impacts

Wetlands in Washington are primarily managed by local jurisdictions through regulations that are implemented on a case-by-case or permit-by-permit basis. Proposed actions are often reviewed and approved without a legal authority or mechanism to assess how previous, relevant decisions may have impacted wetlands and caused cumulative impacts. Each action also is not typically reviewed in the context of impacts to associated landscape processes that may result in cumulative impacts.

On a national level, there is information on the relation between case-by-case decision-making and cumulative impacts. One of the reasons often cited for the failure of site-specific management to adequately protect aquatic resources is the inability of such an approach to address cumulative impacts (Johnston et al. 1990, U.S. Environmental Protection Agency 1999, Dale et al. 2000).

The literature has clearly identified that environmental regulations that are implemented on a permit-by-permit basis have a substantial cumulative impact. This occurs because the permit-by-permit approach fails to identify and account for the landscape processes that create and maintain wetlands (Wissmar and Beschta 1998). In the late 1980s, Bedford and Preston (1988) observed, "The incongruity between the regional scales at which wetland losses are occurring and the project-specific scale at which wetlands are regulated, and also studied, has become obvious." Failure to address the landscape processes results in two types of cumulative impacts (see Table 7-1) that are based on larger, geographic scales - cross-boundary impacts and fragmentation.

Bedford and Preston (1988) note that making decisions on a project-by-project basis fails to evaluate the potential impacts within the spatial and temporal scale within which ecosystems function. They state that, although project-by-project decision-making

> *. . . allows evaluation of the local impacts on resources, it does not allow evaluation of impacts of the project on these resources as a whole, of the total impact on these resources from all anthropogenic disturbances, or of secondary impacts resulting from the interaction of impacts from the project with other anthropogenic disturbances. This is true because the spatial and temporal boundaries of the analysis have not fully enclosed spatial and temporal dynamics of the environmental resources of concern and the anthropogenic activities influencing them.*

These authors recognize that impacts can be generated not only from project-specific actions, but they can also result from actions that occur out of time and outside the vicinity of the activity that may be under scrutiny for a particular project. This results in two types of cumulative impacts described on Table 7-1, time-lags and indirect effects.

Others, such as Everard (1999), are concerned that regulating wetlands and other aquatic resources without considering landscape processes creates the illusion that the resources are being protected by case-by-case management decisions. The ramifications of this misconception include:

- Assumptions by the public that current land-use regulations and management decisions are adequate to protect aquatic systems
- The public perception that protection of aquatic resources is an ongoing financial burden
- The assumption that current regulations are adequate eliminates any incentive or perceived need to assess or modify existing policies and/or regulatory programs

Cumulative effects of decisions made project-by-project: An analogy

Understanding the implication of cumulative impacts from a project-by-project perspective rather than one at a landscape scale may seem abstract given the complexity of how the environment functions in the landscape. The following analogy is offered to provide an alternative description of cumulative effects and the need to manage natural resources using a landscape approach. Credit for the following analogy was given to Gosselink and Lee by Preston and Bedford (1988):

Imagine a Renaissance mosaic of a mother and child, composed of beautiful tiles of various shapes and colors. As it has aged the mosaic has begun to lose tiles. As managers responsible for the mosaic, we have to determine which of the tiles to preserve and reinforce, which to attempt to restore, and which we will allow to be further damaged or even destroyed. Our objective is to attempt to preserve the highest value for the mosaic. Using a tile-by-tile decision method (the project-by-project impacts assessment), each tile would be assessed separately and individually for its intrinsic value. Each decision for a tile would not consider the other nearby tiles, nor even how the tiles fit into the whole image. This strategy would very likely not preserve the image of the mother and child. Yet, it is the image that gives the mosaic its inherent value, not the sum of the individual tiles. If one is to preserve the value of the image, then one needs to be able to determine the relative significance of each individual tile relative to each other tile and to the image as a whole.

7.4.2 Lack of Consistent Plans and Regulations between Jurisdictions as a Possible Cause of Cumulative Impacts

The approach of managing wetlands on a permit-by-permit basis described in the previous section is the best documented cause of cumulative impacts. There are other aspects, however, of the regulatory framework in Washington that can be hypothesized to cause cumulative impacts. A possible source of cumulative impacts is the lack of consistent regulations between jurisdictions to protect and manage landscape processes that occur across jurisdictional boundaries. One jurisdiction may manage water flows from impervious surface, but another one that is further upstream may not manage such flows. Or, one jurisdiction may provide a 200-foot buffer on a reach of riparian wetlands while the adjacent jurisdiction may only provide a 50-foot buffer on the same reach.

In Washington State, most local jurisdictions have development codes that establish the regulatory framework for land use in all areas including wetlands. These codes are based on the objectives developed for each jurisdiction. Adjacent jurisdictions may have quite different objectives for managing the resources and therefore adopt distinctly different codes and regulatory protection. A common inconsistency in regulatory protection is the use of different wetland rating systems that result in variable levels of protection. For example, the city of Tukwila in King County has adopted a rating of wetlands into three categories (Critical Areas Ordinance #2074, December 13, 2004) while King County has adopted a four category rating system (Final Critical Areas Ordinance 15051, Adopted

October 29, 2004). The levels of protection assigned each of the wetland categories is also different. Disparities between rating systems may result in different levels of protection to different portions of the same wetland if it crosses jurisdictional boundaries. It is also quite possible that different buffer widths and different ratios for compensatory mitigation could be required for different parts of the same wetland in adjacent jurisdictions. Such discrepancies therefore can result in cumulative impacts across boundaries.

The failure to address the landscape processes consistently can result in two types of cumulative impacts (see Table 7-1) that are based on larger geographic scales - cross-boundary impacts and fragmentation. The differences in rating systems can result in "cross-boundary" impacts while the example of the different buffers for riparian wetlands would cause impacts from fragmentation.

7.4.3 Implementation of Regulatory Programs at the Local Level as a Possible Cause of Cumulative Impacts

Currently, there is little published information on the possible cumulative impacts that may result from the implementation of regulatory programs by local jurisdictions. For example, there is no documentation on the impacts of:

- Exempting wetlands from protection based on size (e.g., wetlands smaller than ¼ acre are not being regulated at all). Such exemptions can be hypothesized to cause cumulative impacts such as fragmentation and exceeding thresholds of ecosystem viability if there are many small wetlands within a jurisdiction.
- Exempting wetlands based on isolation (e.g., isolated wetlands are those that do not have a surface water connection to other water bodies). Such exemptions can be hypothesized to cause cumulative impacts such as fragmentation and exceeding thresholds of ecosystem viability if there are many isolated wetlands within a jurisdiction.
- Inadequate provisions for protection (e.g., inadequate buffer widths). This can be hypothesized to cause cumulative impacts such as "compounding effect" where an inadequate buffer reduces the habitat for species that need the buffer, as well as by introducing additional disturbances from adjacent development.
- Using standards for compensatory mitigation that are inadequate to ensure replacement of wetland area and/or function. This will result in all types of cumulative impacts because there is a continued loss of wetlands and their functions.

Scientific information synthesized in this document provides guidance on what should be used to effectively protect wetland functions (e.g., landscape approaches, buffers, mitigation standards). See Volume 2 in this two-part series for details regarding specific recommendations. To assess the effectiveness of local programs, we can, therefore, compare the requirements developed by local jurisdictions against what natural resource experts say is needed. The information available suggests that local programs do not

provide the level of planning and protection needed to maintain existing functions and address cumulative impacts.

Two studies in Washington provide more direct information regarding this issue. A King County study (Mockler et al. 1998) concluded that standards for compensatory mitigation implemented by the county were significantly less than what was necessary to meet the goal of no net loss of function or area. In addition, data from the Washington State Department of Community, Trade and Economic Development (CTED) addresses the adequacy of buffer requirements by local governments in Washington. The department collects data on the buffer requirements in critical area ordinances of cities and counties in Washington. In the last such survey in 1999 (Chris Parsons, CTED, personal communications 1999, data are available on request from CTED), the buffers for wetlands were considerably narrower than what the scientific information indicates is necessary to protect many functions. Of the 128 jurisdictions in Washington that specify a numeric buffer width, 99 had buffers of 100 ft or less on wetlands that rate high for their habitat functions. The summary of the scientific information provided in Chapter 5 indicates, however, that most habitat functions are not adequately protected by this buffer width.

Additionally, no city or county in Washington has developed and implemented a landscape-based approach to assessing and protecting wetlands. The scientific information summarized by the Ecological Society of America (Dale et al. 2000) and by the Council of Environmental Quality (1997) indicates that a landscape-based approach is necessary to minimize cumulative impacts.

Thus, it is reasonable to hypothesize that existing wetland protection programs, as implemented in Washington, are not adequately protecting wetland functions and values, and cumulative impacts are resulting.

7.4.4 Relating the Types of Cumulative Impacts to Measures Taken by Local Governments

The list of types of cumulative impacts listed in Table 7-1 can be related to inadequacies of the measures taken to protect wetlands at the local level that have been documented or that can be hypothesized. Examples of the different types of cumulative impacts and examples illustrating these inadequacies are provided in Table 7-2. The inadequacies span the realms of planning, coordination, and regulation.

Table 7-2. Types of cumulative impacts and examples of factors at the local level that might cause the impacts.

Type of Cumulative Impact	Main Characteristics	Examples of Cumulative Impacts	Examples at the Local Level That Might Cause This Impact
Time crowding	Frequent and repetitive disturbances before recovery has occurred from previous disturbance	Reoccurring flooding that drowns vegetation that is not adapted to prolonged inundation	Inadequate storm-water regulations that do not address impacts on wetlands of changes in water regime
Time lags	Impacts of disturbance are delayed	Exposure to toxics	No provision for regulating the use of chemicals on residential lawns draining to wetlands
Space crowding	Impacts are occurring in close proximity to each other	Construction of new highways and high-density commercial zones on both sides of a wetland, resulting in increased noise, lighting, and human presence	No provision for planning at the landscape scale that allows the identification and adequate protection of critical landscape linkages between habitats
Cross-boundary	Impacts occur away from the source	Eutrophication in wetlands and lakes that results from nutrient discharges in upper watershed	Lack of coordination among jurisdictions in controlling nutrient inputs to a watershed
Fragmentation	Changes in the pattern of ecosystems across the landscape	Distribution and size of wetlands across the landscape is reduced	No planning at a landscape scale that identifies key landscape processes and incorporates appropriate management options. Permits are issued on a case-by-case basis
Compounding effects	Impacts arising from multiple sources or pathways	Construction of roads, stormwater facilities, and high density commercial development after an approved rezone	The lack of authority to adequately assess potential long-term effects to landscape processes when changing the potential land use of a parcel or area
Thresholds and triggers	The accumulation of disturbances causes a fundamental change in the behavior of the ecosystem	Increased surface runoff causes streams to be incised and wetlands become disconnected from the floodplain	Permit-by-permit decision making precludes the ability to regulate known or anticipated cumulative effects, unless the regulatory framework is in place

7.5 Chapter Summary and Conclusions

Loss of wetland area and alteration of wetland functions due to human activities are indicators that cumulative impacts are occurring. Wetland losses continue to occur on a national level. The few studies done in the Pacific Northwest suggest that losses continue to occur in the region as well.

The Council on Environmental Quality has identified seven types of cumulative impacts: time crowding, time lags, space crowding, cross-boundary, fragmentation, compounding effects, thresholds and triggers.

Some of the causes of cumulative impacts include the following:

- Permit decisions made on a case-by-case basis. The scientific information available has clearly identified that environmental regulations that are implemented on a permit-by-permit basis have substantial cumulative impacts.
- Lack of consistent regulations between jurisdictions. Local governments vary in the protection they provide to wetlands or to different parts of the same wetland if it crosses political boundaries. Therefore, the same wetland may be subject to a variety of policies and regulatory standards. Differing standards can result in cumulative effects and loss of wetland functions across the landscape.
- Insufficient protection at the local level. Most cities and counties in Washington have historically required buffers that are considerably less than what the research indicates are necessary to protect functions.
- The lack of planning at a larger geographic scale. The scientific information shows that a landscape-based approach is needed to effectively manage wetlands. However, no local government in Washington has developed and implemented a landscape-based approach to assessing and protecting wetlands.

Based on the synthesis of the scientific literature, combined with the knowledge of the standards for protection and how land-use decisions are currently made, it can be hypothesized that current protection programs result in cumulative impacts to wetlands.

Improvements in the way wetlands are protected and managed, and therefore how cumulative impacts can be avoided, is the subject of the second volume in this two-part series. It provides guidance in regard to:

- Implementing a four-part framework for protecting and managing wetlands
- Analyzing the landscape and its wetlands
- Using landscape information in developing plans and policies, and incorporating these into comprehensive planning
- Developing and improving tools typically used in local regulations (rating, buffers, compensatory mitigation, etc)

- Developing and improving non-regulatory tools such as preservation, conservation, and restoration
- Identifying the risks from proposed or existing programs
- Implementing programs
- Monitoring wetland protection and management measures that have been implemented, and adapting programs to address the inadequacies identified

The reader is referred to Volume 2 for suggestions regarding solutions to the problem of cumulative impacts.

References

The following list of references includes those literature sources obtained, reviewed, and synthesized by the Core Team (See Appendix 1-A) that prepared this document. The list also includes references cited in those portions of "Indicators for Monitoring Biological Integrity of Inland, Freshwater Wetlands" (Adamus et al. 2001) that were adapted for use in this synthesis. The references from the adapted portions of the Adamus et al. (2001) document have not all been obtained and reviewed by the Core Team, but they are included here for the convenience of the reader who wishes to consult the original literature for further information. Not all references listed here are cited in the synthesis. Citations listed as "personal communications" in the text are not listed here since the citation contains the information. The references cited in the appendices are listed here and at the end of each appendix. The authors recognize that the format of the references is not always consistent but that this should not prevent interested persons from locating any of the listed references.

Glossary

Terms defined in the context of the sentence in which they appear in this document may not be included in the glossary.

Adventitious roots. Additional roots that develop in some plants, such as willows and alders, as an adaptation to saturated or flooded conditions.

Aquatic resources (systems). Refers to ecological systems where the regular or occasional presence of water is the dominant factor determining the characteristics of the site. Aquatic systems are made up of wetlands, rivers, streams, lakes and other deepwater habitats.

Assessment methods. Methods that generate a number representing an estimate of the performance of a wetland function. The number generated is relative to a predetermined standard (e.g., level of function provided by reference wetlands). Numbers do not reflect an actual level of function performance (Hruby 1999). Examples include the Washington State Methods for Assessing Wetland Functions (WFAM) (Hruby et al. 1999 and 2000) and the HGM approach to wetland function assessment (Brinson et al. 1995).

Biological wetland. A biological wetland is a wetland that meets the three parameter criteria of either the 1987 Corps of Engineers Delineation Manual or the 1997 Washington State Wetlands Identification and Delineation Manual (WAC 173-22-035). Compare to jurisdictional wetland.

Bog. A unique type of wetland dominated by mosses that form organic peat. Bogs form in areas where the climate allows the accumulation of peat to exceed its decomposition. Bog hydrology is dominated by precipitation rather than surface inflow. The plant community is specialized to survive in the nutrient-poor and highly acidic conditions typical of bog systems.

Buffers or buffer areas. Vegetated areas adjacent to wetlands, or other aquatic resources, that can reduce impacts from adjacent land uses through various physical, chemical, and/or biological processes.

Canopy cover. The degree to which the foliage of the highest vegetation layer in a plant community blocks sunlight or obscures the sky.

Class. A grouping based on shared characteristics in a classification scheme. In the Cowardin et al. (1979) classification of wetlands a class is the third level in the 'taxonomy' of wetlands whereas in the Hydrogeomorphic Classification (Brinson 1993) it is the highest taxonomic unit.

Compensatory mitigation. The compensation stage of the mitigation sequence where impacts to the functions and values of wetlands are replaced through creation, restoration, or enhancement of other wetlands. Because regulatory requirements and policies tend to focus on the compensation stage, the term "mitigation" is often used to refer to compensation, which is just one part of the overall mitigation sequence. See *mitigation.*

Conductivity. A measure of the amount of dissolved constituents (ions) in water, based on the water's ability to conduct electricity. See *specific conductance*.

Connectivity. The structures on the landscape that facilitate movement of living organisms between patches or their habitat that are found across the landscape. The movement can occur either within the lifetime of an organism or over a period of generations. The purpose of facilitating movement is to maintain viable populations that allow species and communities of species to persist in time. Connectivity can be achieved via a continuous and linear habitat feature (as in a corridor) or discrete habitat patches comprised of but not limited to individual forests, wetlands, shrub lands, and shorelines.

Conservation easement. A restriction placed on a piece of property to protect the resources (natural or man-made) associated with the parcel. It restricts the type and amount of development that can take place on a parcel of land. For example, the landowner may sell or donate the development rights while retaining the ownership of the property. Easements are recorded on the property deed and are held in trust by a conservation easement "holder" such as a land trust or government agency. The holder polices the terms of the easement for the duration of its existence, which is usually into perpetuity.

Contingency plan. A plan outlining actions that would be triggered if monitoring of a project revealed a problem that would prevent the site from attaining its stated goals, objectives, and performance standards. Contingency plans should identify anticipated problems and the specific maintenance activity that would be implemented to rectify each problem.

Contributing basin. The geographic area from which surface water drains to a particular wetland.

Corixids. A group of aquatic insects commonly called "water boatmen."

Corridor: Corridors are areas that contain relatively undisturbed habitat and/or vegetation that maintain connections for wildlife throughout the landscape. Corridors usually represent linear habitats with the range of environmental functions necessary to permit the movement of animals between larger and more fully functioning habitats. Corridors can include but are not limited to, annual or seasonal migration corridors that connect wintering and breeding habitat, or intra-seasonal corridors that connect foraging and nesting habitat or breeding and dispersal habitat.

Cowardin classification. The first commonly used classification system for wetlands developed in 1979 by the U.S. Fish and Wildlife Service. The Cowardin system classifies wetlands based on water flow, substrate types, vegetation types, and dominant plant species.

Cumulative impacts. The incremental effect of an impact added to other past, present, and reasonably foreseeable future impacts.

Deed restriction (definition from legal dictionary). Clauses in a deed limiting the future uses of the property. Deed restrictions may impose a vast variety of limitations and conditions, for example, they may limit the density of buildings, dictate the types of structures that can be erected or prevent buildings from being used for specific purposes or even from being used at all.

Depressional wetland. A *class* of wetlands in the *hydrogeomorphic classification*. These are wetlands that occur in topographic depressions that exhibit closed contour interval(s) on three sides and elevations that are lower than the surrounding landscape.

Dioxin. A group of several hundred chemical compounds that share certain chemical structures and biological characteristics. They include the chlorinated dibenzo-*p*-dioxins (CDDs), chlorinated dibenzofurans (CDFs), and some polychlorinated biphenyls (PCBs). The term dioxin is also used to refer to a well-studied and toxic dioxin, 2, 3, 7, 8-tetrachlorodibenzo-*p*-dioxin (TCDD).

Disturbance. An event that disrupts the processes or structure of ecological systems. Disturbances may occur naturally (e.g., wildfires, storms, floods) or be caused by human actions (e.g., clearing land, building roads, altering stream channels). The effects of disturbances on ecological systems are controlled in large part by their intensity, duration, frequency, timing, and size and shape of area affected.

Ditch. Any channel that has been specifically dug to facilitate drainage.

Drainage systems. Often called basins, sub-basins, watersheds, or river basins depending on the size of the area. In this document, drainage systems are generally referred to using one of two terms: 1. *Watershed.* A geographic area of land bounded by topographic high points in which water drains to a common destination; and 2. *Contributing basin.* A geographic area from which surface water drains to a particular wetland.

Drawdown. A lowering of the ground-water surface caused by pumping.

Dytiscids. Predaceous diving beetles.

Ecoregion. Geographic regions where climatic conditions are similar and the ecosystems (including wetlands) are relatively homogeneous. Omernik and Gallant (1986) mapped the following ecoregions in Washington: Coast Range, Puget Lowland, Cascades, Eastern Cascades Slopes and Foothills, North Cascades, Columbia Plateau, Blue Mountains, and Northern Rockies.

Ecosystem. A loosely defined assemblage of co-occurring organisms and the geographic location which they inhabit. The term is an operational convenience defined by the user of the term for the convenience of description (Levin 2001). There is no basic geographic scale associated with the term ecosystem, and that also has to be defined by a user. For example, the term can be used to describe the micro-organisms co-occurring in a spoonful of soil (soil ecosystem) at one end of the scale to the ecosystem of the world that encompasses all organisms on the planet.

Ecotone. An area that is transitional between two different types of ecosystems and has some of the features of both. Wetlands are often characterized as being ecotones between aquatic and terrestrial ecosystems.

Edge. The boundary where habitats meet or where successional stages of plant communities come together.

Emergence trap. A device placed over the water or sediment in a wetland to capture flying aquatic insects as they emerge from their non-flying larval state into their winged adult form.

Environmental processes. The same as *landscape processes*.

Eutrophication. The undesirable overgrowth of vegetation caused by high concentrations of plant nutrients in bodies of water, especially nitrogen and phosphorous, often as a result of human activities.

Evapotranspiration. The combination of water that is evaporated from the surface and that is transpired from the leaves of plants as part of their metabolic process.

Fen. A type of wetland that is similar to a bog, containing accumulated peat. Fens support marsh-like vegetation including sedges and wildflowers. Fens differ from bogs in their plant communities, hydrology, and water chemistry. They are fed by groundwater and are not as acidic as bogs.

Flats. A class of wetlands in the *hydrogeomorphic classification*. These are wetlands that occur in topographically flat areas that are hydrologically isolated from surrounding ground or surface water. They are primarily maintained by precipitation.

Forb. Any herbaceous plant that is not a grass or sedge.

Forested wetland. A wetland *class* in the Cowardin classification where woody plants taller than 20 feet form the dominant cover. Shrubs often form a second layer beneath the forest canopy, with a layer of herbaceous plants growing beneath the shrubs.

Fragmentation. The breaking up of ecosystems into patches of habitat that are separated by areas altered by human land uses. Fragmentation always consists of both the reduction in the area of the original habitat and a change in spatial configuration of what remains.

Functions. The physical, biological, chemical, and geologic interactions among different components of the environment. See *wetland functions*.

Functional feeding group. A group of animals (aquatic insects, birds, etc) that feed in a similar way. For example, insects that scrape algae from rocks in a stream are called scrapers; those that shred leaf material are caked shredders; and those that filter small particles from the water column are filter feeders.

Furans. A chemical substance resulting from the manufacture of organic compounds, such as nylon.

Geomorphic setting. The topographic location of a site within the surrounding landscape and the geology that underlies it.

Geomorphology. The geologic composition and structure of a landscape—its topography, landforms, soils, and geology.

Hemipterans. A group of insects with straw-like, sucking mouth parts.

Herbaceous (stratum). A layer of non-woody vegetation, usually less than 6 feet (2 m) tall.

Hertz (Hz). A unit of frequency equal to one cycle per second.

Humic. Of or pertaining to humus, which consists of partially or wholly decayed plant matter.

Hydrodynamics. Refers to the movement of water and its capacity to do work. There are three qualitative categories of hydrodynamics: (1) vertical fluctuations of the water levels or water table, (2) unidirectional surface or near-surface flows that range from strong currents contained in channels to slow sheet flow down a slope, and (3) bidirectional flows resulting from tides or wind-driven currents in lakes.

Hydrogeomorphic (HGM) classification. A system used to classify wetlands based on the position of the wetland in the landscape (geomorphic setting), the water source for the wetland, and the flow and fluctuation of the water once in the wetland.

Hydroperiod. The pattern of water level fluctuations in a wetland. Includes the depth, frequency, duration, and timing of inundation or flooding. Patterns can be daily, monthly, seasonal, annual, or longer term.

Impact. Changes to the environment that are caused by human disturbances. Impacts can be either beneficial or detrimental to the ecosystem, environmental process, or species.

Interior (species). Animal species that require the conditions found on the interior of a habitat type and which are subject to disturbance in areas toward the edges of that habitat. For example, forest interior birds find optimum conditions within the center of a forested area where they are not subject to domestic pets, noise, severe weather, or other disturbances that penetrate the outer forest edge.

Jurisdictional wetland. A wetland that is regulated by the provisions of the law under the jurisdiction of one or more federal, state, or local agencies. Not all areas of the landscape that have the biological characteristics of wetlands are regulated or jurisdictional wetlands.

Lacustrine. Pertaining to lakes or lake shores.

Lacustrine (lake) fringe wetlands. A wetland *class* under the *hydrogeomorphic classification*. These are wetlands that occur at the margins of topographic depressions in which surface water is greater than 8 hectares (20 acres) and greater than 2 meters deep in western Washington and 3 meters in eastern Washington.

Landscape processes. Environmental factors that occur at larger geographic scales such as basins, sub-basins, and watersheds. Processes are dynamic and usually represent the movement of a basic environmental characteristic such as water, sediment, nutrients and chemicals, energy, or animals and plants. The interaction of landscape processes with the physical environment creates specific geographic locations where groundwater is recharged, flood waters are stored, stream water is oxygenated, pollutants are removed, and wetlands are created.

Landscape scale. The geographic scale that encompasses the broader landscape (i.e., large areas such as basins, sub-basins, watersheds, and habitat corridors). Also see *site scale* and *large scale*.

Large scale. Large in scope. This term is used specifically to indicate geographic areas that extend beyond the boundaries of an individual site, wetland, or resource. Please note that this term has the opposite meaning when it is used in cartography. Large scale maps are ones that cover a smaller geographic area than a small scale map.

Large woody debris (LWD). Large pieces of downed wood, such as logs, rootwads, and limbs, that are in or near a body of water. LWD provides habitat structure for fish and other aquatic organisms.

Lentic. Having slow moving or still water, such as a pond or lake (as compared to lotic – having running water, such as a river or stream).

Metapopulation. A group of local populations between which individuals can migrate.

Microbe. A microscopic organism, such as a bacterium.

Microhm. A unit of measure describing the resistance of a substance to electrical current.

MilliSiemens. A unit of measure for conductivity. See *specific conductance*.

Mitigation (or mitigation sequencing). Mitigation is a series of actions that requires addressing each action, or step, in a particular order. This sequence of steps is used to reduce the severity of negative impacts from activities that potentially affect wetlands. Mitigation involves the following: 1. Avoiding the impact altogether by not taking a certain action or parts of an action; 2. Minimizing impacts by limiting the degree or magnitude of the action and its implementation, by using appropriate technology, or by taking affirmative steps, such as project redesign, relocation, or timing, to avoid or reduce impacts; 3. Rectifying the impact by repairing, rehabilitating, or restoring the affected environment; 4. Reducing or eliminating the impact over time by preservation and maintenance operations during the life of the action; 5. Compensating for the impact by replacing, enhancing, or providing substitute resources or environments; and 6. Monitoring the required compensation and taking remedial action when necessary (WAC 197.11.768). See *compensatory mitigation*.

Natural Heritage (Wetlands) (as defined by the Natural Heritage Program of the Washington State Department of Natural Resources). Wetlands that are either high quality undisturbed wetlands or wetlands that support threatened, endangered, or sensitive plant species.

Niche. The area within a habitat occupied by an organism; the set of functional relationships of an organism or population to the environment it occupies.

PCBs. Polychlorinated biphenyls, a type of toxic chemical compound once widely used in electrical equipment. See *dioxin*.

Phreatic zone. The area above the groundwater table.

Redox (potential). Reduction-oxidation potential, or a measure of the potential movement of electrons in a system. Reduction refers to the chemical process whereby molecules of a substance gain an electron. Oxidation refers to loss of electrons. Measuring the redox potential of a wetland soil provides information about the types of chemical reactions that are occurring in the soil, and thus whether the soil is more aerobic (contains oxygen) or anaerobic (lacks oxygen).

Richness. The number of different species of organisms present in a community.

Riparian. The strip of land adjacent to a body of water that is transitional between the aquatic system and the upland. Some riparian areas contain wetlands.

Riverine wetlands. A *class* of wetlands in the *hydrogeomorphic classification*. Wetlands that occur in floodplains and riparian corridors in association with stream or river channels where there is frequent overbank flooding.

Rotifers. Minute organisms that live in fresh and salt water. A crown of hair-like structures (cilia) propels them through the water.

Roughness. The amount of friction or resistance a surface provides against water flow. For example, an area containing shrubs and downed branches has greater roughness than a mowed lawn.

Site processes. Environmental factors that occur within the wetland itself or within its buffer. The interactions of site processes with landscape processes define how a wetland functions.

Site scale. The geographic scale that encompasses the area within the boundary of a single wetland and its immediate surroundings. Also see *landscape scale*.

Slope wetlands. A *class* of wetlands in the *hydrogeomorphic classification***.** These are wetlands that occur on the slopes of hills or valleys. The principal water source is usually seepage from groundwater.

Specific conductance. A measure of electrical conductivity standardized to 25^{o}C. Use of specific conductance accounts for the fact that the conductivity of water changes as its temperature changes. It is measured in units of milliSiemens per centimeter.

Sub-basin. A smaller drainage basin that is part of a larger drainage basin or watershed. For example, the watershed of a large river may be composed of several sub-basins, one for each of the river's tributaries.

Temporal loss (of functions). The concept that there is a time lag between the loss of existing wetland functions through human or natural disturbance and the reestablishment of functions over time.

Tidal Fringe wetlands. A *class* of wetlands in the *hydrogeomorphic classification*. Wetlands that occur on continental margins where marine waters are greater than 2 meters deep and more than 8 hectares (20 acres) in size.

Trophic level. A concept used to describe feeding levels in a foodweb. Plants fill the first trophic level by utilizing sunlight to create carbohydrates and other compounds. Plants are consumed by plant-eating animals (herbivores) in the second trophic level, which in turn become food for predators in the next trophic level, and so on.

Values. See *wetland values***.**

Watershed. A geographic area of land bounded by topographic high points in which water drains to a common destination.

Wetland functions. The physical, biological, chemical, and geologic interactions among different components of the environment that occur within a wetland. Wetlands perform many valuable functions and these can be grouped into three categories: functions that improve water quality, functions that change the water regime in a watershed such as flood storage, and functions that provide habitat for plants and animals.

Wetland rating. Also called a wetland rating system. is a tool for dividing or grouping wetlands into groups that have similar needs for protection. One method used in Washington is the Washington State wetland rating systems (Hruby 2004a,b), which places wetlands in categories based on their rarity, sensitivity, our inability to replace them, and their functions.

Wetland Values. Wetland processes, characteristics, or attributes that are considered to benefit society.

Appendix 1-A
Team Guiding Production of Volume 1

An interagency team (the Core Team) guided all aspects of and participated in the search and reading of the scientific literature, wrote the synthesis, and produced Volume 1. Additional members were added during the production of Volume 2 (see Volume 2).

For Volume 1, the team consisted of staff from the Washington State Department of Ecology, the Washington State Department of Fish and Wildlife, the U.S. Environmental Protection Agency, and Sheldon and Associates, the consulting firm hired to assist with production. Additional Ecology staff served as authors (see the list of authors on the title page of this document). The editor was included on the Core Team in the later stages of production of draft of Volume 1 and was involved through the development of the review draft of Volume 2.

The Core Team included the following individuals (alphabetical by last name):

Teri Granger	Washington State Department of Ecology (coordinator)
Kim Harper	Sheldon and Associates[1]
Tom Hruby	Washington State Department of Ecology
Katherine March	Washington State Department of Fish and Wildlife
Andy McMillan	Washington State Department of Ecology
Sara Noland	2N Publications (editor of the draft)
Ralph Rogers	U.S. Environmental Protection Agency
Dyanne Sheldon	Sheldon and Associates
Erik Stockdale	Washington State Department of Ecology

[1] Currently with the Washington State Department of Ecology.

Appendix 1-B

Characteristics of a Valid Scientific Process

The characteristics of a valid scientific process in the context of "best available science" are defined below, as quoted directly from WAC 365-195-905:

1. ***Peer review.*** *The information has been critically reviewed by other persons who are qualified scientific experts in that scientific discipline. The criticism of the peer reviewers has been addressed by the proponents of the information. Publication in a refereed scientific journal usually indicates that the information has been appropriately peer-reviewed.*

2. ***Methods.*** *The methods that were used to obtain the information are clearly stated and able to be replicated. The methods are standardized in the pertinent scientific discipline or, if not, the methods have been appropriately peer-reviewed to assure their reliability and validity.*

3. ***Logical conclusions and reasonable inferences.*** *The conclusions presented are based on reasonable assumptions supported by other studies and consistent with the general theory underlying the assumptions. The conclusions are logically and reasonably derived from the assumptions and supported by the data presented. Any gaps in information and inconsistencies with other pertinent scientific information are adequately explained.*

4. ***Quantitative analysis.*** *The data have been analyzed using appropriate statistical or quantitative methods.*

5. ***Context.*** *The information is placed in proper context. The assumptions, analytical techniques, data, and conclusions are appropriately framed with respect to the prevailing body of pertinent scientific knowledge.*

6. ***References.*** *The assumptions, analytical techniques, and conclusions are well referenced with citations to relevant, credible literature and other pertinent existing information.*

Information derived from one of these sources can be considered scientific information if it possesses the required characteristics shown in Table 1B-1.

Table 1B-1. Source and characteristics of scientific information.

Sources of Scientific Information	Characteristics					
	Peer Review	**Methods**	**Logical Conclusions & Reasonable Inferences**	**Quantitative Analysis**	**Context**	**References**
A. **Research**. Research data collected and analyzed as part of a controlled experiment (or other appropriate method) to test a specific hypothesis.	X	X	X	X	X	X
B. **Monitoring**. Monitoring data collected periodically over time to determine a resource trend or evaluate a management program.	NA	X	X	Y	X	X
C. **Inventory**. Inventory data collected from an entire population or population segment (e.g., individuals in a plant or animal species) or an entire ecosystem or ecosystem segment (e.g., the species in a particular wetland).	NA	X	X	Y	X	X
D. **Survey**. Survey data collected from a statistical sample from a population or ecosystem.	NA	X	X	Y	X	X
E. **Modeling**. Mathematical or symbolic simulation or representation of a natural system. Models generally are used to understand and explain occurrences that cannot be directly observed.	X	X	X	X	X	X
F. **Assessment**. Inspection and evaluation of site-specific information by a qualified scientific expert. An assessment may or may not involve collection of new data.	NA	X	X	NA	X	X
G. **Synthesis**. A comprehensive review and explanation of pertinent literature and other relevant existing knowledge by a qualified scientific expert.	X	X	X	NA	X	X
H. **Expert Opinion**. Statement of a qualified scientific expert based on his or her best professional judgment and experience in the pertinent scientific discipline. The opinion may or may not be based on site-specific information.	NA	NA	X	NA	X	X

X = Characteristic must be present for information derived to be considered scientifically valid and reliable.
Y = Presence of characteristic strengthens scientific validity and reliability of information derived, but is not essential to ensure scientific validity and reliability.
NA = The characteristic does not apply to the source type. For example, monitoring data are not typically peer reviewed.

Appendix 1-C

Methods Used for Searching and Reviewing the Literature

Searching the Literature

To begin the literature review for Volume 1, personal bibliographies were solicited from a small number of professionals known to have extensive libraries on wetlands in the Pacific Northwest. Other published reference lists were reviewed for relevant documents. In addition to the specified reference lists, computer searches were conducted of databases that are publicly available using a variety of keywords. Table 1C-1 lists the sources of reference lists and the names of the databases searched, as well as the approximate number of documents contained in each source.

Table 1C-2 lists the keywords that were used in the searches of computer databases. This list was developed by the Core Team and expanded based on comments from focus groups (see Chapter 1 for information on focus groups). The searches were done combining the word "wetland" plus one of the keywords. The words in the last column were used to exclude wetland types not covered by this report. Specific wetland types not found in Washington and known to be very dissimilar from Washington wetlands were also excluded, as were estuarine and marine wetlands. Lists resulting from the searches of the computer databases were compiled into a ProCite® database for the project.

Table 1C-1. Summary of reference lists and databases searched for Volume 1.

List Source	Approx. No. of Documents	Notes
Personal Bibliographies		
Dr. Paul Adamus, EPA	1,600	Broad range of documents
Dr. Tom Hruby, WA Ecology	600	Broad range of documents, many focus on wetland functions
Mary Kentula, EPA	170	Focus on wetland mitigation, management, policy effectiveness
Dr. Klaus Richter, King County	3,500	Focus on amphibians w/Pacific NW emphasis
Published Reference Lists		
Management recommendations for WA priority habitats: freshwater wetlands and fresh deepwater (Morgan 1998)	640	Focus on wildlife and aquatic habitats
Management recommendations for WA priority habitats: riparian (Knutson and Naef 1997)	550	Focus on riparian habitats, not necessarily wetlands
Managing for enhancement of riparian and wetland areas of the Western U.S.: an annotated bibliography (Koehler and Thomas 2000)	1,900	Broad application to western U.S.; many documents not relevant to Pac. NW
Classification and management of aquatic, riparian and wetland sites on the national forests of Eastern Washington (Kovalchik 2004)	400	Focus on eastside and forested areas
Effects of urbanization on pond-breeding amphibians: an annotated literature review (Ostergaard 2000)	100	Focus on amphibians and urban effects
Database Searches		
Keyword searches of various databases	9,800	Databases searched included Ovid, ProQuest, Biosis, Dissertation Abstracts, Agricola, Current Contents, Biological Abstracts
Total	**~17,860**	**Total includes an unknown number of duplicates among the various sources**

Table 1C-2. Keywords used in searching computer databases of literature.

Base Word	Keywords		Exclusions
Wetland	Aesthetics Agriculture Alkali Alluvial Amphibians Aquifer Recharge Arid Land Artesian Birds Bog Buffers Compensation Conservation Cumulative Impacts Development Disturbed Dynamic Economics Enhancement Erosion Farmed Fen Fish Floodplain Fluvial Functions Geology Geomorphology Grazing Groundwater Habitat Hydraulic Hydric Hydrology Hyporheic Industrial Inventory Invertebrates Irrigation Isolated	Land Use Landscape Maintenance Mammals Mapping Mining Mitigation Mollusks Monitoring Nutrients Perched Policy Public Access Recreation Regulation Reptiles Residential Restoration River Rural Seasonal Septic Slope Soils Spatial Stewardship Stormwater Transportation Corridors Urban Utility Corridors Values Variation Vegetation Types Vernal Pools (not Calif.) Water Quality Water Regime Wells Wildlife	Bottomland Hardwood California Vernal Pools Estuarine Intertidal Lacustrine Marine Mississippi Floodplain Mudflats Salt Marsh Saltwater

Reviewing, Sorting, and Prioritizing the Reference Lists

All reference lists were reviewed by one or more of the Core Team members. From these lists, the Core Team selected those documents that were determined to be relevant to the project, based solely on the title of the article and its date. Those marked documents were then prioritized using a two-tiered system in which those considered most critical to the project were designated as those to be obtained first. Eventually, attempts were made

to obtain all the documents on the lists that were believed to be relevant based on their titles. In addition, references were found while individual authors searched for subjects for which information was lacking. These references are provided in the list of references cited in the report.

Criteria Used to Identify Articles Relevant to the Project

When screening lists of articles, the Core Team used the following criteria to determine, through reading the title and looking at the date, which were relevant to the project and should be obtained. Those that were deemed a "definite yes" were those that were:

- Related to wetland protection and management
- Applied to Washington or the Pacific Northwest
- Were out of region but dealt with land uses
- The only paper on a subject

Those that were rejected out-right were those that were:

- Very old and superceded by newer information
- Related to estuarine and marine systems, which were not going to be covered in the document
- Primarily scientific minutia that weren't useful to managing and protecting wetlands
- Not related because of region
- Related to wetlands and waste-water treatment, which was not going to be covered in the document

Obtaining & Reading Documents & Writing the Report

Of the more than 17,000 documents on all lists used, copies of over 1,400 documents were obtained after review of the titles and dates, as prioritized using the screening process described above. References were skimmed and those dealing with Washington or the Pacific Northwest and with practical application to the protection and management of wetlands were prioritized for reading.

Each reader summarized the article in the ProCite® database. Searches of the database or the original articles were used by each author to write their portions of the draft document. Additional articles were discovered during the course of writing the draft document. These references were not included in the ProCite® database.

The documents used to write the synthesis included scientific journal articles, government publications, technical books, and other sources, all of which meet the definition and characteristics of BAS in WAC 365-195-905 (see Appendix 1-B and Chapter 1). Conference proceedings and personal communications were occasionally used when no other information was available. In most cases, we were unable to ascertain to what level these additional sources were peer reviewed.

For the most part, available documents from the past ten years were used as the primary sources for this report. It was assumed that this more recent literature would incorporate relevant science from the preceding years. Older documents were used in instances where they had not been superseded by more recent studies.

In a few instances, we used unpublished data collected during the calibration of the Washington State wetland function assessment methods and the Washington State wetland rating systems. These data have not been published in scientific journals. However, these observations reported as "unpublished data" in Volume 1, were collected in the field by interdisciplinary teams of wetland experts and used to support and calibrate the assessment methods and the wetland rating system. The methods and rating system have been extensively reviewed and field tested by peer experts, as well as the public. The data were offered for review upon request during public review and continue to be available on request. See Chapter 1 for discussion of the occasional use of hypotheses and assumptions made by the authors based on the literature or their professional experience.

Obtaining References Suggested by Reviewers

A questionnaire was circulated with the review draft of the document. The draft of Volume 1 was reviewed by peer experts. In addition, we invited anyone who so desired to review it. Reviewers were asked to provide additional references that we may have missed, for topics for which we lacked information, or to support suggested changes to the document. Many references were provided and a screening process was used to prioritize and obtain references. See the document containing our responses to comments for a table listing the references that were suggested, the references which were obtained, and notes of explanation for each reference suggested. (The Comments and Responses for Volume 1 can be found at http://www.ecy.wa.gov/biblio/0506007.html.)

Establishing a Repository

The ProCite® database is not available for general use because of technical reasons and the time and money required in making it accessible to a wide variety of users and their varied software programs. However, paper copies of many of the articles reviewed for the synthesis of the science are being held in an archive at the Washington State Department of Ecology. The archive is accessible to the public by appointment.

A number of theses, dissertations, and books are not included in the archive, as well as some articles in private libraries, due to copyright laws and the limited options for purchasing some documents. In these cases, borrowed copies were used and returned, with only the title pages and tables of contents copied for the archive.

Appendix 1-D

Reviewers of Volume 1

Name of Individual or Organization	Affiliation at the Time of Review (if individual)
Paul Adamus, PhD	Private Consultant
Jeff Azerrad, Wildlife Biologist	WA State Department of Fish and Wildlife
Joann Bartlett, PWS	Wiltermood Associates
Doug Beyerlein, PE	Aqua Terra Consultants
Elizabeth Binney, PhD, PWS	ATSI
Catherine Conolly, PWS and Teresa H. Vanderburg, PWS (submitted comments jointly)	Adolfson Associates
Brent Davis, Wetland Biologist	Clark County Community Development Department
Tim Determan, Puget Sound Ambient Monitoring Program Coordinator	WA State Department of Health
Donald F. Flora	Private citizen
Richard R. Horner, PhD	University of Washington
Richard Jack	WA State Department of Ecology
Jim Kelley, PhD	Parametrix, Inc.
Bernard L (Bud) Kovalchik, retired U.S. Forest Service -- Eastern Washington Area Ecologist	Kovalchik Riparian Wetland Consulting
Ivan Lines, Regional Biologist	Ducks Unlimited, Inc.
Scott Luchessa, Certified Ecologist, MS.	Ecological Solutions, Inc.
Chris L. McAuliffe, Ecologist	Private citizen, retired from the Seattle District of the Army Corps of Engineers
Elliot Menashe, Environmental Consultant	Greenbelt Consulting
Jeff Meyer, PWS	Parametrix, Inc.
Jim Mitchell, PE, PWS	Mitchell Consultants L.L.C.
Lyn Morgan-Hill, Natural Resources Specialist	Whatcom County Planning and Development
Francis Naglich	Ecological Land Services, Inc.
Scott Williams, Land Planner	Puget Sound Energy
Klaus Richter, PhD, PWS	King County Department of Natural Resources
Scott J. Rozenbaum, PWS, Certified Professional Soil Scientist	Rozewood Environmental Services, Inc.

Megan White	WA State Department of Transportation
Bob Zeigler	WA State Department of Fish and Wildlife
Unidentified Individual	

Appendix 2-A

Methods for Organizing and Grouping Information about Wetlands

The following information is adapted from Hruby (1999).

Many groups including federal and state agencies have been developing techniques for analyzing wetland functions ever since wetlands were first subject to regulation in the 1970s. The motivation for developing such methods has primarily been the need to predict the effects of alterations to wetlands and set appropriate requirements for compensatory mitigation.

Methods for organizing knowledge about wetlands have been called classifications, categorizations, characterizations, ratings, assessments, and evaluations. These groupings are meant to indicate the type of information a method provides. Unfortunately, the scientific community has been sloppy in the use of these terms to the extent of misnaming many of the analytical tools developed. Users of methods developed for analyzing wetlands should be aware of some of these problems with definitions. Standard definitions for analytical methods based on Webster's Seventh New Collegiate Dictionary (1963) are described below.

Classification/categorization—a systematic grouping into categories according to established criteria or shared characteristics. The two most common wetland classifications are those of Cowardin et al. (1979), which is based on shared characteristics of vegetation and water regime, and the hydrogeomorphic classification (Brinson 1993b), which is based on shared characteristics of geomorphic setting and water regime. The criteria used for grouping are generally not linked to specific functions, and thus classifications are not true methods for assessing functions. They can, however, provide a basis on which to develop assessment methods (Brinson 1995).

Characterization—a grouping by a distinguishing trait, quality, or property. For example, the Oregon method (Roth et al. 1993) characterizes wetlands by the properties: "provides" a specific function; "has the potential to provide" a function; or "does not provide" a function. These are three distinct attributes that give some information about whether a wetland performs a function, but no information is generated about levels of performance. The Washington State wetland rating systems are characterizations based on five properties (sensitivity to disturbance, rarity, importance, ability to replicate, and relative level of functioning) (Hruby 2004a, b).

Rating—classification based on a grade. Ratings usually group wetlands using the qualitative grades of high, medium, or low on a variety of scales such as the performance of a function or its value. The wetland evaluation technique or WET (Adamus et al. 1987) is probably the most widely used rating method.

Assessment—an estimate or determination of importance or value. This is the first level at which numbers are generated to represent an estimate of performance or value of a function. All commonly used "rapid" numeric methods fall into this category. These methods only provide an assessment that is relative to some predetermined standard. They do not provide an assessment of actual levels of performance or value. The term *assessment* is one of the most commonly misused words in the lexicon of wetland scientists. Almost any method developed is now called an assessment, regardless of whether it might actually be a categorization, a rating, or a true assessment.

Evaluation—a determination or fixing of value. The fixing of value for any item is based on having a generally acceptable currency. Up to now the only currency used has been monetary, and evaluations of wetland functions have most often tried to generate dollar values based on different types of economic models such as the travel cost method, random utility model, hedonic techniques, contingent valuation method (Titre and Henderson 1989, Lipton et al. 1995), or willingness-to-pay method (Farber and Costanza 1987).

Appendix 2-B

Associations between Species of Wildlife and Wetlands in Washington and Oregon

This appendix shows the level of association between species of wildlife and wetlands in Washington and Oregon in a table. The data are copied directly from the tabulated data on a computer disk provided with Johnson and O'Neil (2001).

Four types of wetland habitat were identified in the document by Johnson and O'Neil. The definitions for these types are summarized below and are from Chappell et al. (2001) and O'Neil and Johnson (2001). Detailed descriptions of the geographic distribution, physical setting, landscape setting, structure, and composition are given in Chappell et al. (2001).

Herbaceous Wetlands (list of species starts on page 4)

Wetlands with the following vegetation types:

- Graminoid Wet Meadow
- Freshwater Aquatic Bed
- Herbaceous and Sedge Wetlands

This habitat is called palustrine emergent wetlands in Cowardin et al. (1979).

Westside Riparian – Wetlands (list of species starts on page 15)

Wetlands with the following vegetation types:

- *Alnus viridis* ssp. *sinuata – Acer circinatum* Shrublands
- Westside Riparian and Wetland Deciduous Forests
- *Picea sitchensis* Wetland Forests and Woodlands
- *Tsuga heterphylla-Thuja plicata* Coniferous Wetlands
- Westside Riparian/Wetland Shrublands
- Shrub/herbaceous Sphagnum Bogs
- Wooded Bogs

This habitat includes all palustrine forested wetlands and scrub-shrub wetlands at lower elevations west of the Cascades as well as a small subset of persistent emergent wetlands, those with sphagnum bogs. However, drier portions of this habitat in riparian flood plains may not qualify as wetlands according to the Cowardin definition.

Montane Coniferous Wetlands (list of species starts on page 29)

Wetlands with the following vegetation types:

- Westside Montane Coniferous Wetlands
- *Picea engelmannii* Forested Wetlands

This habitat includes nearly all the wettest forests within the *Abies amabilis* and *Tsuga mertensiana* zones of western Washington and most of the wet forests in the *Tsuga heterophylla* and *Abies lasiocarpa* zones of eastern Oregon and Washington.

Eastside (Interior) Riparian – Wetlands (list of species starts on page 38)

Wetlands with the following vegetation types:

- Eastside Midmontane *Alnus incana-Salix* spp. Riparian Shrublands
- Eastside Lowland Riparian Shrublands
- Eastside *Populus balsamifera* spp. *trichocarpa*
- *Alnus rhombifolia* Riparian
- *Pinus ponderosa* Riparian Woodlands
- *Populus tremuloides* Riparian/Wetland Forests and Woodlands

This habitat is called palustrine scrub-shrub and palustrine forest in Cowardin and includes some palustrine emergent in the National Wetland Inventory.

Definitions for the Types of Association

(copied from O'Neil and Johnson 2001)

Closely Associated. A species is widely known to depend on a habitat for part or all of its life history requirements. Identifying this association implies that the species has an essential need for this habitat for its maintenance and viability. Some species may be closely associated with more than one habitat; others may be closely associated with only one habitat.

Generally Associated. A species exhibits a high degree of adaptability and may be supported by a number of habitats. In other words, the habitats play a supportive role for its maintenance and viability.

Present. A species demonstrates occasional use of a habitat. The habitat provides marginal support to the species for its maintenance and viability.

The expert panelists developing this list also assigned an overall "confidence rating" to the categorization for each species within each habitat type. The confidence ratings were high (e.g., many peer or published accounts), moderate, and low (e.g., few or no published accounts).

PLEASE NOTE: The following tables of data do not contain the Latin name of the species. The original tables on Johnson and O'Neil (2001, data on CD) did not have the Latin names although they do have information on each individual species and its Latin name in other databases on the computer disk.

Wildlife Species Found in Herbaceous Wetlands

Amphibians Associated with Herbaceous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Bullfrog	Closely Associated	Feeds and Breeds	High	Requires warm-water ponds, marshes, or river/stream backwaters for breeding.
Columbia Spotted Frog	Closely Associated	Feeds and Breeds	High	Rare or absent where predatory fish or bullfrogs occur. Requires shallow water in wet meadows or stream/pond edges with abundant aquatic vegetation for breeding.
Great Basin Spadefoot	Closely Associated	Feeds and Breeds	High	Requires ponds or temporary rain-filled depressions for breeding.
Long-toed Salamander	Closely Associated	Feeds and Breeds	High	Rare or absent where predatory fish are occur. Requires ponds, shallow lake edges, seasonal pools (like elk wallows) or slow streams for breeding.
Northern Leopard Frog	Closely Associated	Feeds and Breeds	High	Requires ponds or lake edges with dense aquatic and emergent vegetation for breeding.
Northwestern Salamander	Closely Associated	Feeds and Breeds	High	Requires ponds or stream backwaters for breeding.
Oregon Spotted Frog	Closely Associated	Feeds and Breeds	High	Rare or absent where predatory fish or bullfrogs occur. Requires shallow water in wet meadows or stream/pond edges with abundant aquatic vegetation for breeding.
Pacific Chorus (Tree) Frog	Closely Associated	Feeds and Breeds	High	Requires ponds, seasonal pools, temporary rain-filled depressions or slow streams for breeding.
Red-legged Frog	Closely Associated	Feeds and Breeds	High	Requires cool-water ponds, lake edges or slow streams for breeding.
Rough-skinned Newt	Closely Associated	Feeds and Breeds	High	Requires ponds or stream backwaters with abundant aquatic vegetation for breeding.
Tiger Salamander	Closely Associated	Feeds and Breeds	High	Rare or absent where predatory fish occur. Requires warm ponds or shallow lake edges for breeding.
Western Toad	Closely Associated	Feeds and Breeds	High	Requires ponds or shallow lake edges for breeding.
Woodhouse's Toad	Closely Associated	Feeds and Breeds	High	Requires warm, shallow water in ponds, lakes, or slow streams for breeding.
Cascades Frog	Generally Associated	Feeds and Breeds	Moderate	Range limited to Cascade axis fringe. Requires bogs or ponds with cold springs for breeding.

Birds Associated with Herbaceous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
American Avocet	Closely Associated	Feeds and Breeds	High	None noted.
American Bittern	Closely Associated	Feeds and Breeds	High	None noted.
American Black Duck	Closely Associated	Feeds and Breeds	Low	None noted.
American Coot	Closely Associated	Feeds and Breeds	High	None noted.
American Wigeon	Closely Associated	Feeds and Breeds	High	None noted.
Baird's Sandpiper	Closely Associated	Feeds	Moderate	None noted.
Barn Swallow	Closely Associated	Feeds	High	Can nest anywhere buildings, bridges, or overhanging cliffs occur in close proximity to water.
Black Tern	Closely Associated	Feeds and Breeds	High	None noted.
Black-crowned Night-heron	Closely Associated	Feeds	High	Requires shrubs or trees for nesting.
Black-necked Stilt	Closely Associated	Feeds and Breeds	High	None noted.
Blue-winged Teal	Closely Associated	Feeds and Breeds	High	None noted.
Bufflehead	Closely Associated	Feeds	High	Nests in tree cavities near ponds or lakes.
Canada Goose	Closely Associated	Feeds and Breeds	High	None noted.
Canvasback	Closely Associated	Feeds and Breeds	High	None noted.
Caspian Tern	Closely Associated	Feeds	High	None noted.
Cattle Egret	Closely Associated	Feeds	High	Requires shrubs or trees for nesting.
Cinnamon Teal	Closely Associated	Feeds and Breeds	High	None noted.
Clark's Grebe	Closely Associated	Feeds and Breeds	High	Nests placed on a floating platform of fresh and decaying vegetation in shallow water.
Common Loon	Closely Associated	Feeds and Breeds	Moderate	Nests in emergent vegetation at lake edges. No nesting confirmed in Oregon.
Common Snipe	Closely Associated	Feeds and Breeds	High	None noted.
Common Yellowthroat	Closely Associated	Feeds and Breeds	High	None noted.

Birds Associated with Herbaceous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Dunlin	Closely Associated	Feeds	Moderate	None noted.
Eared Grebe	Closely Associated	Feeds and Breeds	Moderate	Nests placed on a floating platform of fresh and decaying vegetation in shallow water.
Forster's Tern	Closely Associated	Feeds and Breeds	High	None noted.
Franklin's Gull	Closely Associated	Feeds and Breeds	High	Breeds at Mahleur Lake, Oregon.
Gadwall	Closely Associated	Feeds and Breeds	High	None noted.
Great Blue Heron	Closely Associated	Feeds	High	Requires trees for nesting.
Great Egret	Closely Associated	Feeds	High	Requires tall shrubs or trees for nesting.
Greater White-fronted Goose	Closely Associated	Feeds	High	None noted
Greater Yellowlegs	Closely Associated	Feeds	High	Has bred at least four times at Downy Lake, Wallowa County, Oregon.
Green Heron	Closely Associated	Feeds	High	Requires shrubs or trees for nesting.
Green-winged Teal	Closely Associated	Feeds and Breeds	High	None noted.
Horned Grebe	Closely Associated	Feeds and Breeds	Moderate	Nests placed on a floating platform of fresh and decaying vegetation in shallow water.
Least Bittern	Closely Associated	Feeds and Breeds	High	Rare breeder in Oregon; does not occur in Washington.
Least Sandpiper	Closely Associated	Feeds	Moderate	None noted.
Lesser Scaup	Closely Associated	Feeds and Breeds	High	None noted.
Lesser Yellowlegs	Closely Associated	Feeds	High	None noted.
Lincoln's Sparrow	Closely Associated	Feeds and Breeds	Moderate	None noted.
Long-billed Dowitcher	Closely Associated	Feeds	High	None noted.
Mallard	Closely Associated	Feeds and Breeds	High	None noted.
Marsh Wren	Closely Associated	Feeds and Breeds	Moderate	None noted.
Mute Swan	Closely Associated	Feeds and Breeds	Moderate	This is an introduced species which breeds only in urban wetlands.
Northern Pintail	Closely Associated	Feeds and Breeds	High	None noted.

Birds Associated with Herbaceous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Northern Rough-winged Swallow	Closely Associated	Feeds	High	Requires burrows in dirt banks, usually next to water, for nesting.
Northern Shoveler	Closely Associated	Feeds and Breeds	High	None noted.
Pectoral Sandpiper	Closely Associated	Feeds	Moderate	None noted.
Pied-billed Grebe	Closely Associated	Feeds and Breeds	High	Nests placed on a floating platform of fresh and decaying vegetation in shallow water.
Redhead	Closely Associated	Feeds and Breeds	High	None noted.
Red-necked Grebe	Closely Associated	Feeds and Breeds	High	Nests placed on a floating platform of fresh and decaying vegetation in shallow water.
Red-winged Blackbird	Closely Associated	Feeds and Breeds	High	None noted.
Ross's Goose	Closely Associated	Feeds	High	None noted.
Ruddy Duck	Closely Associated	Feeds and Breeds	High	None noted.
Sandhill Crane	Closely Associated	Feeds and Breeds	High	None noted.
Short-eared Owl	Closely Associated	Feeds and Breeds	Moderate	None noted.
Snow Goose	Closely Associated	Feeds	High	None noted.
Snowy Egret	Closely Associated	Feeds	High	Requires tall shrubs or trees for nesting.
Solitary Sandpiper	Closely Associated	Feeds	Moderate	None noted.
Sora	Closely Associated	Feeds and Breeds	High	None noted.
Swamp Sparrow	Closely Associated	Feeds	High	None noted.
Tree Swallow	Closely Associated	Feeds	Moderate	Requires snags not far from open water for nesting.
Tricolored Blackbird	Closely Associated	Feeds and Breeds	High	None noted.
Trumpeter Swan	Closely Associated	Feeds and Breeds	High	None noted.
Tundra Swan	Closely Associated	Feeds	High	None noted.
Virginia Rail	Closely Associated	Feeds and Breeds	High	None noted.

Birds Associated with Herbaceous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Western Grebe	Closely Associated	Feeds and Breeds	High	Nests placed on a floating platform of fresh and decaying vegetation in shallow water.
Western Sandpiper	Closely Associated	Feeds	Moderate	None noted.
White-faced Ibis	Closely Associated	Feeds and Breeds	High	None noted.
Willet	Closely Associated	Feeds and Breeds	High	None noted.
Wilson's Phalarope	Closely Associated	Feeds and Breeds	High	None noted.
Yellow Rail	Closely Associated	Feeds and Breeds	High	None noted.
Yellow-headed Blackbird	Closely Associated	Feeds and Breeds	High	None noted.
American Goldfinch	Generally Associated	Feeds	High	None noted.
American Kestrel	Generally Associated	Feeds	High	None noted.
American Robin	Generally Associated	Feeds	High	None noted.
American White Pelican	Generally Associated	Feeds	High	Feeds in open water areas of wetlands.
Bald Eagle	Generally Associated	Feeds	High	None noted.
Bank Swallow	Generally Associated	Feeds	High	Requires burrows in dirt banks, usually next to water, for nesting.
Barn Owl	Generally Associated	Feeds	High	None noted.
Barrow's Goldeneye	Generally Associated	Feeds	Moderate	Nests in tree cavities near ponds or lakes.
Black-chinned Hummingbird	Generally Associated	Feeds	Low	None noted.
Bobolink	Generally Associated	Feeds and Breeds	Moderate	None noted.
Brewer's Blackbird	Generally Associated	Feeds and Breeds	Moderate	None noted.
Brown-headed Cowbird	Generally Associated	Feeds and Breeds	High	None noted.
Burrowing Owl	Generally Associated	Feeds	High	None noted.
California Gull	Generally Associated	Feeds and Breeds	Moderate	None noted.
Cliff Swallow	Generally Associated	Feeds	High	Can nest anywhere rimrock, over-hanging cliffs, buildings or bridges occur in close proximity to water.

Birds Associated with Herbaceous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Common Nighthawk	Generally Associated	Feeds	Moderate	None noted.
Common Raven	Generally Associated	Feeds	High	None noted.
Cooper's Hawk	Generally Associated	Feeds	High	None noted.
Double-crested Cormorant	Generally Associated	Reproduces	High	None noted.
Eastern Kingbird	Generally Associated	Feeds	Moderate	None noted.
Eurasian Wigeon	Generally Associated	Feeds	High	None noted.
European Starling	Generally Associated	Feeds	Moderate	Requires snags or trees with cavities or buildings with crevices for nesting. Most likely to use this habitat where adjacent to agriculture or urban habitats.
Glaucous Gull	Generally Associated	Feeds	Low	None noted.
Golden-crowned Sparrow	Generally Associated	Feeds	Moderate	None noted.
Great Gray Owl	Generally Associated	Feeds	High	None noted.
Great Horned Owl	Generally Associated	Feeds	High	None noted.
Gyrfalcon	Generally Associated	Feeds	Moderate	None noted.
Herring Gull	Generally Associated	Feeds	High	None noted.
Hooded Merganser	Generally Associated	Feeds	High	Nests in tree cavities near ponds or lakes.
Killdeer	Generally Associated	Feeds and Breeds	Moderate	None noted.
Long-billed Curlew	Generally Associated	Feeds	Moderate	None noted.
Long-eared Owl	Generally Associated	Feeds	Moderate	None noted.
Northern Goshawk	Generally Associated	Feeds	Moderate	None noted.
Northern Harrier	Generally Associated	Feeds and Breeds	High	None noted.
Palm Warbler	Generally Associated	Feeds	Low	Only along the coast.
Peregrine Falcon	Generally Associated	Feeds	High	None noted.

Birds Associated with Herbaceous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Purple Martin	Generally Associated	Feeds	Low	None noted.
Red-tailed Hawk	Generally Associated	Feeds	High	None noted.
Ring-billed Gull	Generally Associated	Feeds and Breeds	Moderate	None noted.
Ring-necked Duck	Generally Associated	Feeds and Breeds	High	None noted.
Ring-necked Pheasant	Generally Associated	Feeds	High	None noted.
Rough-legged Hawk	Generally Associated	Feeds	Moderate	None noted.
Savannah Sparrow	Generally Associated	Feeds and Breeds	High	None noted.
Sharp-shinned Hawk	Generally Associated	Feeds	High	None noted.
Song Sparrow	Generally Associated	Feeds and Breeds	High	None noted.
Spotted Sandpiper	Generally Associated	Feeds and Breeds	Moderate	None noted.
Swainson's Hawk	Generally Associated	Feeds	Moderate	None noted.
Thayer's Gull	Generally Associated	Feeds	Moderate	None noted.
Turkey Vulture	Generally Associated	Feeds	High	None noted.
Upland Sandpiper	Generally Associated	Feeds and Breeds	High	Has been found at Sycan Marsh, Lake County, Oregon.
Vaux's Swift	Generally Associated	Feeds	Low	None noted.
Violet-green Swallow	Generally Associated	Feeds	Moderate	None noted.
White-crowned Sparrow	Generally Associated	Feeds	Moderate	None noted.
White-throated Swift	Generally Associated	Feeds	Low	Could forage over herbaceous wetlands incidently, such as those found in desert playas.
American Crow	Present	Feeds	High	None noted.
American Dipper	Present	Feeds	Moderate	None noted.
American Pipit	Present	Feeds	Moderate	Winter only.
Bewick's Wren	Present	Feeds	Low	None noted.
Black Swift	Present	Feeds	Low	Black swifts are long-distance foragers that may travel many miles from breeding sites and take advantage of flying insects caught in updrafts over just about any habitat.

Birds Associated with Herbaceous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Black-billed Magpie	Present	Feeds	High	None noted.
Black-capped Chickadee	Present	Feeds	Moderate	None noted.
Calliope Hummingbird	Present	Feeds	Low	None noted.
Cedar Waxwing	Present	Feeds	Moderate	None noted.
Common Goldeneye	Present	Feeds	Moderate	Nests in tree cavities near ponds or lakes.
Golden Eagle	Present	Feeds	High	None noted.
House Finch	Present	Feeds	Moderate	Uses this habitat where it is not too far from urban or agricultural areas.
Lapland Longspur	Present	Feeds	Low	None noted.
Loggerhead Shrike	Present	Feeds	Moderate	None noted.
Merlin	Present	Feeds	Low	None noted.
Northern Pygmy-owl	Present	Feeds	High	None noted.
Northern Shrike	Present	Feeds	High	None noted.
Pine Siskin	Present	Feeds	Low	None noted.
Ruby-crowned Kinglet	Present	Feeds	High	Winter only.
Rufous Hummingbird	Present	Feeds	Moderate	None noted.
Snowy Owl	Present	Feeds	Moderate	None noted.
Western Meadowlark	Present	Feeds	Low	None noted.
Western Screech-owl	Present	Feeds	Moderate	None noted.
Wood Duck	Present	Feeds	Moderate	Nests in tree cavities near ponds or lakes.
Yellow-rumped Warbler	Present	Feeds	Low	None noted.

Mammals Associated with Herbaceous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
American Beaver	Closely Associated	Feeds and Breeds	High	None noted.
Deer Mouse	Closely Associated	Feeds and Breeds	High	None noted.
Long-tailed Vole	Closely Associated	Feeds and Breeds	High	None noted.
Meadow Vole	Closely Associated	Feeds and Breeds	Low	None noted.
Mink	Closely Associated	Feeds	Moderate	None noted.
Montane Vole	Closely Associated	Feeds and Breeds	High	None noted.
Moose	Closely Associated	Feeds	High	None noted.
Muskrat	Closely Associated	Feeds and Breeds	Moderate	None noted.
Northern Bog Lemming	Closely Associated	Feeds and Breeds	Moderate	Cold, wet bogs above 5000 feet.

Mammals Associated with Herbaceous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Northern River Otter	Closely Associated	Feeds and Breeds	High	None noted.
Nutria	Closely Associated	Feeds and Breeds	Moderate	None noted.
Pallid Bat	Closely Associated	Feeds	High	None noted.
Raccoon	Closely Associated	Feeds	Moderate	None noted.
Townsend's Vole	Closely Associated	Feeds and Breeds	High	None noted.
Western Harvest Mouse	Closely Associated	Feeds and Breeds	High	None noted.
Yuma Myotis	Closely Associated	Feeds	High	None noted.
Big Brown Bat	Generally Associated	Feeds	Moderate	None noted.
Black Bear	Generally Associated	Feeds	High	None noted.
Black-tailed Deer	Generally Associated	Feeds	High	None noted.
Bobcat	Generally Associated	Feeds	Moderate	None noted.
Brazilian Free-tailed Bat	Generally Associated	Feeds	High	None noted.
California Myotis	Generally Associated	Feeds	High	None noted.
Columbian White-tailed Deer	Generally Associated	Feeds	High	None noted.
Coyote	Generally Associated	Feeds	High	None noted.
Feral Pig	Generally Associated	Feeds and Breeds	Moderate	Eastern Oregon wet meadows.
Fringed Myotis	Generally Associated	Feeds	Low	None noted.
Hoary Bat	Generally Associated	Feeds	Low	None noted.
Keen's Myotis	Generally Associated	Feeds	Low	None noted.
Little Brown Myotis	Generally Associated	Feeds	High	None noted.
Long-eared Myotis	Generally Associated	Feeds	Moderate	None noted.
Long-legged Myotis	Generally Associated	Feeds	Moderate	None noted.
Long-tailed Weasel	Generally Associated	Feeds	Moderate	None noted.
Mountain Caribou	Generally Associated	Feeds	Moderate	None noted.

Mammals Associated with Herbaceous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Mountain Lion	Generally Associated	Feeds	High	None noted.
Mule Deer	Generally Associated	Feeds	High	None noted.
Pacific Jumping Mouse	Generally Associated	Feeds and Breeds	Moderate	None noted.
Pacific Water Shrew	Generally Associated	Feeds and Breeds	Moderate	Closely tied to water.
Rocky Mountain Elk	Generally Associated	Feeds	High	None noted.
Roosevelt Elk	Generally Associated	Feeds	High	None noted.
Shrew-mole	Generally Associated	Feeds and Breeds	High	None noted.
Silver-haired Bat	Generally Associated	Feeds	Low	None noted.
Spotted Bat	Generally Associated	Feeds	Moderate	None noted.
Striped Skunk	Generally Associated	Feeds	Moderate	None noted.
Townsend's Big-eared Bat	Generally Associated	Feeds	Low	None noted.
Townsend's Mole	Generally Associated	Feeds and Breeds	High	None noted.
Vagrant Shrew	Generally Associated	Feeds and Breeds	Moderate	None noted.
Western Jumping Mouse	Generally Associated	Feeds and Breeds	Low	None noted.
Western Small-footed Myotis	Generally Associated	Feeds	Low	None noted.
White-tailed Deer (Eastside)	Generally Associated	Feeds	High	None noted.
Yellow-bellied Marmot	Generally Associated	Feeds	Low	Requires talus slopes, lava fields, rimrock, or boulder fields in close proximity to grassy openings or meadows.
Common Porcupine	Present	Feeds	Moderate	Needs large shrubs for food.
Feral Horse	Present	Feeds	Low	None noted.
Grizzly Bear	Present	Feeds	Low	None noted.
Preble's Shrew	Present	Feeds and Breeds	Low	None noted.
Wild Burro	Present	Feeds	Low	In southeastern Oregon, this habitat is mostly unavailable due to the fact that they are situated primarily on private lands and are fenced.

Reptiles Associated with Herbaceous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Common Garter Snake	Closely Associated	Feeds and Breeds	High	None noted.
Pacific Coast Aquatic Garter Snake	Present	Feeds and Breeds	Moderate	Uses this habitat where near marshes, streams, rivers, ponds or lakes.
Painted Turtle	Closely Associated	Feeds	Moderate	None noted.
Red-eared Slider Turtle	Closely Associated	Feeds	High	None noted.
Snapping Turtle	Closely Associated	Feeds	Moderate	None noted.
Western Pond Turtle	Closely Associated	Feeds	High	None noted.
Western Terrestrial Garter Snake	Generally Associated	Feeds	High	None noted.

Wildlife Species Found in Westside Riparian - Wetlands

Amphibians Associated with Westside Riparian - Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Bullfrog	Closely Associated	Feeds and Breeds	High	Requires warm-water ponds, marshes, or river/stream backwaters for breeding.
Cascade Torrent Salamander	Closely Associated	Feeds and Breeds	High	Requires very cold, clear seeps, springs, and small streams for breeding.
Columbia Torrent Salamander	Closely Associated	Feeds and Breeds	High	Requires very cold, clear seeps, springs, and small streams for breeding.
Cope's Giant Salamander	Closely Associated	Feeds and Breeds	Moderate	Requires clear, cold steep-gradient streams with a streambed of gravel, boulders and large logs for breeding.
Long-toed Salamander	Closely Associated	Feeds and Breeds	High	Rare or absent where predatory fish are occur. Requires ponds, shallow lake edges, seasonal pools (like elk wallows) or slow streams for breeding.
Northwestern Salamander	Closely Associated	Feeds and Breeds	High	Requires ponds or stream backwaters for breeding.
Olympic Torrent Salamander	Closely Associated	Feeds and Breeds	High	Requires very cold, clear seeps, springs, and small streams for breeding.
Oregon Spotted Frog	Closely Associated	Feeds and Breeds	High	Rare or absent where predatory fish or bullfrogs occur. Requires shallow water in wet meadows or stream/pond edges with abundant aquatic vegetation for breeding.
Pacific Chorus (Tree) Frog	Closely Associated	Feeds and Breeds	High	Requires ponds, seasonal pools, temporary rain-filled depressions or slow streams for breeding.
Pacific Giant Salamander	Closely Associated	Feeds and Breeds	Moderate	Requires small to mid-sized streams with a streambed of gravel, boulders and large logs for breeding.
Red-legged Frog	Closely Associated	Feeds and Breeds	High	Requires cool-water ponds, lake edges or slow streams for breeding.
Rough-skinned Newt	Closely Associated	Feeds and Breeds	High	Requires ponds or stream backwaters with abundant aquatic vegetation for breeding.
Southern Torrent Salamander	Closely Associated	Feeds and Breeds	High	Requires very cold, clear seeps, springs, and small streams for breeding.
Tailed Frog	Closely Associated	Feeds and Breeds	Moderate	Requires clear, cold steep-gradient streams for breeding.

Amphibians Associated with Westside Riparian - Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Western Toad	Closely Associated	Feeds and Breeds	High	None noted.
Black Salamander	Generally Associated	Feeds and Breeds	Low	Requires logs, woody debris, or moist talus with woody debris.
California Slender Salamander	Generally Associated	Feeds and Breeds	Moderate	Requires logs.
Cascades Frog	Generally Associated	Feeds and Breeds	Moderate	Requires bogs or ponds with cold springs for breeding.
Dunn's Salamander	Generally Associated	Feeds and Breeds	Moderate	Requires moist or wet rock outcrops, talus, gravel, boulders, or rock crevices
Ensatina	Generally Associated	Feeds and Breeds	High	Requires logs, woody debris, or moist talus with woody debris.
Foothill Yellow-legged Frog	Generally Associated	Feeds and Breeds	High	Requires still-water or gentle gradient portions of streams for breeding.
Oregon Slender Salamander	Generally Associated	Feeds and Breeds	Moderate	Requires large logs, woody debris, or moist talus with woody debris.
Van Dyke's Salamander	Generally Associated	Feeds and Breeds	Moderate	Requires moist talus, rock outcrops, logs, seeps, or woody debris and rocks along streams.
Western Red-backed Salamander	Generally Associated	Feeds and Breeds	High	Requires moist or shaded talus, rocks, or large logs. Occasionally uses springs or stream edges.

Birds Associated with Westside Riparian - Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
American Black Duck	Closely Associated	Feeds and Breeds	Low	None noted.
American Dipper	Closely Associated	Feeds and Breeds	High	None noted.
Band-tailed Pigeon	Closely Associated	Feeds and Breeds	Moderate	None noted.
Barn Swallow	Closely Associated	Feeds and Breeds	High	Can nest anywhere buildings, bridges, or overhanging cliffs occur in close proximity to water.
Belted Kingfisher	Closely Associated	Feeds and Breeds	High	None noted.
Black Phoebe	Closely Associated	Feeds and Breeds	Moderate	None noted.
Black-throated Gray Warbler	Closely Associated	Feeds and Breeds	High	None noted.

Birds Associated with Westside Riparian - Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Bullock's Oriole	Closely Associated	Feeds and Breeds	Moderate	None noted.
Cliff Swallow	Closely Associated	Feeds and Breeds	High	Can nest anywhere rimrock, overhanging cliffs, buildings or bridges occur in close proximity to water.
Common Merganser	Closely Associated	Feeds and Breeds	High	Nests in tree cavities near large lakes or rivers.
Common Yellowthroat	Closely Associated	Feeds and Breeds	High	None noted.
Downy Woodpecker	Closely Associated	Feeds and Breeds	Moderate	None noted.
European Starling	Closely Associated	Feeds and Breeds	High	Requires snags or trees with cavities or buildings with crevices for nesting. Most likely to use this habitat where adjacent to agriculture or urban habitats.
Great Blue Heron	Closely Associated	Feeds and Breeds	High	None noted.
Green Heron	Closely Associated	Feeds and Breeds	High	None noted.
Harlequin Duck	Closely Associated	Feeds and Breeds	High	None noted.
Hooded Merganser	Closely Associated	Feeds and Breeds	High	Nests in tree cavities.
Lesser Goldfinch	Closely Associated	Feeds and Breeds	Moderate	None noted.
Lincoln's Sparrow	Closely Associated	Feeds and Breeds	High	None noted.
Mallard	Closely Associated	Feeds and Breeds	High	None noted.
Mourning Dove	Closely Associated	Feeds and Breeds	High	None noted.
Northern Rough-winged Swallow	Closely Associated	Feeds and Breeds	High	Requires burrows in dirt banks, usually next to water, for nesting.
Northern Waterthrush	Closely Associated	Feeds and Breeds	High	None noted.
Purple Finch	Closely Associated	Feeds and Breeds	Moderate	None noted.
Red-eyed Vireo	Closely Associated	Feeds and Breeds	Moderate	Range of red-eyed vireo overlaps that of large black cottonwood groves.

Birds Associated with Westside Riparian - Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Ring-necked Duck	Closely Associated	Feeds and Breeds	Moderate	None noted.
Ruffed Grouse	Closely Associated	Feeds and Breeds	High	None noted.
Solitary Sandpiper	Closely Associated	Feeds	High	None noted.
Spotted Sandpiper	Closely Associated	Feeds and Breeds	Moderate	None noted.
Swamp Sparrow	Closely Associated	Feeds	High	None noted.
Tree Swallow	Closely Associated	Feeds and Breeds	Moderate	Requires snags not far from open water for nesting.
Warbling Vireo	Closely Associated	Feeds and Breeds	High	None noted.
Western Screech-owl	Closely Associated	Feeds and Breeds	High	None noted.
Willow Flycatcher	Closely Associated	Feeds and Breeds	Moderate	None noted.
Wilson's Warbler	Closely Associated	Feeds and Breeds	High	None noted.
Wood Duck	Closely Associated	Feeds and Breeds	High	Nests in tree cavities.
Yellow Warbler	Closely Associated	Feeds and Breeds	High	None noted.
Yellow-breasted Chat	Closely Associated	Feeds and Breeds	Moderate	None noted.
Allen's Hummingbird	Generally Associated	Feeds and Breeds	Low	None noted.
American Crow	Generally Associated	Feeds and Breeds	High	None noted.
American Goldfinch	Generally Associated	Feeds and Breeds	High	None noted.
American Kestrel	Generally Associated	Feeds and Breeds	High	None noted.
American Robin	Generally Associated	Feeds and Breeds	High	None noted.
American Wigeon	Generally Associated	Feeds	High	None noted.
Bald Eagle	Generally Associated	Feeds and Breeds	High	None noted.
Barn Owl	Generally Associated	Feeds and Breeds	High	Requires cliffs, caves, rimrock, or tree cavities for nesting.

Birds Associated with Westside Riparian - Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Barred Owl	Generally Associated	Feeds and Breeds	Moderate	None noted.
Bewick's Wren	Generally Associated	Feeds and Breeds	Moderate	None noted.
Black Swift	Generally Associated	Feeds and Breeds	Low	Requires suitable cliffs behind waterfalls for breeding.
Black-capped Chickadee	Generally Associated	Feeds and Breeds	Moderate	None noted.
Black-crowned Night-heron	Generally Associated	Feeds	High	Only one and maybe two known breeding sites exist west of the Cascades, though historically a large breeding colony occurred near Portland.
Black-headed Grosbeak	Generally Associated	Feeds and Breeds	High	None noted.
Brewer's Blackbird	Generally Associated	Feeds and Breeds	Moderate	None noted.
Brown Creeper	Generally Associated	Feeds and Breeds	Moderate	None noted.
Brown-headed Cowbird	Generally Associated	Feeds and Breeds	High	None noted.
Bufflehead	Generally Associated	Feeds and Breeds	High	Nests in tree cavities.
Bushtit	Generally Associated	Feeds and Breeds	Moderate	None noted.
California Quail	Generally Associated	Feeds and Breeds	High	Uses this habitat where adjacent to more open habitats.
Cedar Waxwing	Generally Associated	Feeds and Breeds	High	None noted.
Chestnut-backed Chickadee	Generally Associated	Feeds and Breeds	Moderate	None noted.
Common Nighthawk	Generally Associated	Feeds	Moderate	None noted.
Common Raven	Generally Associated	Feeds and Breeds	High	None noted.
Cooper's Hawk	Generally Associated	Feeds and Breeds	High	None noted.
Dark-eyed Junco	Generally Associated	Feeds and Breeds	High	None noted.
Evening Grosbeak	Generally Associated	Feeds and Breeds	Moderate	None noted.

Birds Associated with Westside Riparian - Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Fox Sparrow	Generally Associated	Feeds	High	Winter only.
Golden-crowned Kinglet	Generally Associated	Feeds and Breeds	High	None noted.
Golden-crowned Sparrow	Generally Associated	Feeds	Moderate	None noted.
Gray Jay	Generally Associated	Feeds and Breeds	Moderate	None noted.
Great Egret	Generally Associated	Feeds and Breeds	Moderate	None noted.
Great Horned Owl	Generally Associated	Feeds and Breeds	High	None noted.
Greater Yellowlegs	Generally Associated	Feeds	Low	None noted.
Green-winged Teal	Generally Associated	Feeds	High	None noted.
Hairy Woodpecker	Generally Associated	Feeds and Breeds	Moderate	None noted.
Hermit Thrush	Generally Associated	Feeds	High	None noted.
Hermit Warbler	Generally Associated	Feeds and Breeds	Moderate	None noted.
House Wren	Generally Associated	Feeds and Breeds	Moderate	None noted.
Hutton's Vireo	Generally Associated	Feeds and Breeds	High	None noted.
Killdeer	Generally Associated	Feeds and Breeds	Moderate	None noted.
Lazuli Bunting	Generally Associated	Feeds and Breeds	Moderate	None noted.
Least Flycatcher	Generally Associated	Feeds and Breeds	Low	Found nesting near Monroe, Snohomish County, Washington.
Lesser Yellowlegs	Generally Associated	Feeds	Low	None noted.
Macgillivray's Warbler	Generally Associated	Feeds and Breeds	High	None noted.
Merlin	Generally Associated	Feeds and Breeds	Moderate	None noted.
Mountain Quail	Generally Associated	Feeds and Breeds	Moderate	None noted.

Birds Associated with Westside Riparian - Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Nashville Warbler	Generally Associated	Feeds and Breeds	Moderate	None noted.
Northern Flicker	Generally Associated	Feeds and Breeds	Moderate	None noted.
Northern Goshawk	Generally Associated	Feeds	Moderate	None noted.
Northern Pygmy-owl	Generally Associated	Feeds and Breeds	High	None noted.
Olive-sided Flycatcher	Generally Associated	Feeds and Breeds	Moderate	None noted.
Orange-crowned Warbler	Generally Associated	Feeds and Breeds	High	None noted.
Osprey	Generally Associated	Feeds and Breeds	High	None noted.
Pacific-slope Flycatcher	Generally Associated	Feeds and Breeds	Moderate	None noted.
Palm Warbler	Generally Associated	Feeds	Moderate	Only along the coast.
Peregrine Falcon	Generally Associated	Feeds	High	None noted.
Pied-billed Grebe	Generally Associated	Feeds and Breeds	High	Uncertain about the frequency of breeding in this type of habitat.
Pileated Woodpecker	Generally Associated	Feeds and Breeds	Moderate	None noted.
Pine Siskin	Generally Associated	Feeds and Breeds	Moderate	None noted.
Purple Martin	Generally Associated	Feeds and Breeds	Low	None noted.
Red-breasted Nuthatch	Generally Associated	Feeds and Breeds	Moderate	None noted.
Red-breasted Sapsucker	Generally Associated	Feeds and Breeds	Moderate	None noted.
Red-shouldered Hawk	Generally Associated	Feeds and Breeds	Low	None noted.
Red-tailed Hawk	Generally Associated	Feeds and Breeds	High	None noted.
Red-winged Blackbird	Generally Associated	Feeds and Breeds	Low	None noted.
Ring-necked Pheasant	Generally Associated	Feeds and Breeds	High	None noted.
Ruby-crowned Kinglet	Generally Associated	Feeds	High	Winter only.

Birds Associated with Westside Riparian - Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Rufous Hummingbird	Generally Associated	Feeds and Breeds	Moderate	None noted.
Savannah Sparrow	Generally Associated	Feeds and Breeds	Moderate	None noted.
Song Sparrow	Generally Associated	Feeds and Breeds	High	None noted.
Spotted Towhee	Generally Associated	Feeds and Breeds	Moderate	None noted.
Steller's Jay	Generally Associated	Feeds and Breeds	Moderate	None noted.
Swainson's Thrush	Generally Associated	Feeds and Breeds	High	None noted.
Townsend's Warbler	Generally Associated	Feeds and Breeds	High	None noted.
Turkey Vulture	Generally Associated	Feeds and Breeds	High	Requires rocky outcrops, small caves, boulder piles, ledges on high cliffs or large hollow logs for nesting.
Vaux's Swift	Generally Associated	Feeds and Breeds	Moderate	None noted.
Violet-green Swallow	Generally Associated	Feeds and Breeds	Moderate	None noted.
Western Tanager	Generally Associated	Feeds and Breeds	Moderate	None noted.
Western Wood-pewee	Generally Associated	Feeds and Breeds	Moderate	None noted.
White-breasted Nuthatch	Generally Associated	Feeds and Breeds	Moderate	None noted.
White-crowned Sparrow	Generally Associated	Feeds and Breeds	Moderate	None noted.
Wild Turkey	Generally Associated	Feeds	Moderate	Low elevation sites only; likely uses this habitat more for cover than feeding.
Winter Wren	Generally Associated	Feeds and Breeds	Moderate	None noted.
Yellow-rumped Warbler	Generally Associated	Feeds	Moderate	None noted.
American Redstart	Present	Feeds and Breeds	Low	None noted.
American Tree Sparrow	Present	Feeds	Moderate	None noted.
Anna's Hummingbird	Present	Feeds and Breeds	Low	None noted.

Birds Associated with Westside Riparian - Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Ash-throated Flycatcher	Present	Feeds and Breeds	Low	Requires an oak component.
Blue Grouse	Present	Feeds and Breeds	Moderate	None noted.
Bohemian Waxwing	Present	Feeds	Moderate	Occurs in Westside habitats only during irruption years.
Canada Goose	Present	Feeds and Breeds	Moderate	None noted.
Chipping Sparrow	Present	Feeds	Low	None noted.
Common Redpoll	Present	Feeds	Moderate	Only in Skagit and Whatcom counties, Washington.
Double-crested Cormorant	Present	Feeds and Breeds	High	None noted.
House Finch	Present	Feeds and Breeds	Moderate	Uses this habitat where it is not too far from urban or agricultural areas.
Lewis's Woodpecker	Present	Feeds	Moderate	May use as wintering habitat in Oregon; historically occurred in this habitat in western Washington.
Northern Harrier	Present	Feeds and Breeds	High	None noted.
Northern Saw-whet Owl	Present	Feeds and Breeds	Moderate	None noted.
Red Crossbill	Present	Feeds and Breeds	Moderate	None noted.
Rough-legged Hawk	Present	Feeds	High	None noted.
Snowy Egret	Present	Feeds	Moderate	None noted.
Townsend's Solitaire	Present	Feeds	Moderate	None noted.
Veery	Present	Feeds and Breeds	High	None noted.
Western Scrub-Jay	Present	Feeds and Breeds	Moderate	None noted.
White-tailed Kite	Present	Feeds and Breeds	Moderate	None noted.
White-winged Crossbill	Present	Feeds	Low	None noted.

Mammals Associated with Westside Riparian - Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
American Beaver	Closely Associated	Feeds and Breeds	High	None noted.
Deer Mouse	Closely Associated	Feeds and Breeds	High	None noted.
Dusky-footed Woodrat	Closely Associated	Feeds and Breeds	Moderate	None noted.
Fisher	Closely Associated	Feeds and Breeds	Moderate	None noted.
Fog Shrew	Closely Associated	Feeds and Breeds	High	None noted.
Long-tailed Vole	Closely Associated	Feeds and Breeds	High	None noted.
Mink	Closely Associated	Feeds and Breeds	Moderate	None noted.
Mountain Beaver	Closely Associated	Feeds and Breeds	High	None noted.
Muskrat	Closely Associated	Feeds and Breeds	Moderate	None noted.
Northern River Otter	Closely Associated	Feeds and Breeds	High	None noted.
Nutria	Closely Associated	Feeds and Breeds	Moderate	None noted.
Pacific Jumping Mouse	Closely Associated	Feeds and Breeds	High	None noted.
Pacific Shrew	Closely Associated	Feeds and Breeds	High	None noted.
Pacific Water Shrew	Closely Associated	Feeds and Breeds	High	Closely tied to water.
Raccoon	Closely Associated	Feeds and Breeds	Moderate	None noted.
Southern Red-backed Vole	Closely Associated	Feeds and Breeds	High	None noted.
Water Shrew	Closely Associated	Feeds and Breeds	High	Lead a semi-aquatic life and require cold, clear water in small streams or ponds with abundant cover in the form of rocks, overhanging banks, etc.
Water Vole	Closely Associated	Feeds and Breeds	Low	None noted.
White-footed Vole	Closely Associated	Feeds and Breeds	Moderate	None noted.

Mammals Associated with Westside Riparian - Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Yuma Myotis	Closely Associated	Feeds and Breeds	High	More closely associated with water than other bat species. Uses caves, mines, loose bark and bark crevices typically close to water.
Big Brown Bat	Generally Associated	Feeds and Breeds	Moderate	Requires snags, caves, mines, rock crevices, or bridges for breeding and roosting.
Black Bear	Generally Associated	Feeds and Breeds	High	None noted.
Black-tailed Deer	Generally Associated	Feeds and Breeds	High	None noted.
Bobcat	Generally Associated	Feeds and Breeds	Moderate	None noted.
Broad-footed Mole	Generally Associated	Feeds and Breeds	Moderate	None noted.
Brush Rabbit	Generally Associated	Feeds and Breeds	Moderate	None noted.
California Myotis	Generally Associated	Feeds and Breeds	High	Uses rock crevices, hollow trees, mines or caves for breeding.
Coast Mole	Generally Associated	Feeds and Breeds	Moderate	None noted.
Columbian Mouse	Generally Associated	Feeds and Breeds	High	None noted.
Columbian White-tailed Deer	Generally Associated	Feeds and Breeds	High	None noted.
Common Porcupine	Generally Associated	Feeds and Breeds	Moderate	None noted.
Coyote	Generally Associated	Feeds and Breeds	High	None noted.
Creeping Vole	Generally Associated	Feeds and Breeds	High	None noted.
Eastern Cottontail	Generally Associated	Feeds and Breeds	Low	Likely uses this habitat where adjacent to urban or agricultural habitats.
Ermine	Generally Associated	Feeds and Breeds	Low	None noted.
Fringed Myotis	Generally Associated	Feeds and Breeds	Low	Requires caves, mines or rock crevices.
Gray Fox	Generally Associated	Feeds and Breeds	Low	None noted.
Hoary Bat	Generally Associated	Feeds	Low	Requires trees for roosting, but forages in openings and at edges of forests.

Mammals Associated with Westside Riparian - Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Keen's Myotis	Generally Associated	Feeds and Breeds	Low	Little studied; hard to distinguish from long-eared myotis. Likely requires tree cavites for breeding, caves for hibernacula.
Little Brown Myotis	Generally Associated	Feeds and Breeds	High	Uses caves, mines, or hollow trees, often near water.
Long-eared Myotis	Generally Associated	Feeds and Breeds	Moderate	Uses caves, mines, hollow trees, loose bark or rock crevices.
Long-legged Myotis	Generally Associated	Feeds and Breeds	Moderate	Uses caves or mines as hibernacula. Uses hollow trees, loose bark or rock crevices for maternity colonies.
Long-tailed Weasel	Generally Associated	Feeds and Breeds	Moderate	None noted.
Mountain Lion	Generally Associated	Feeds and Breeds	High	None noted.
Northern Flying Squirrel	Generally Associated	Feeds and Breeds	High	None noted.
Pallid Bat	Generally Associated	Feeds	Low	None noted.
Red Fox	Generally Associated	Feeds and Breeds	Low	Non-native Red fox.
Rocky Mountain Elk	Generally Associated	Feeds and Breeds	High	None noted.
Roosevelt Elk	Generally Associated	Feeds and Breeds	High	None noted.
Shrew-mole	Generally Associated	Feeds and Breeds	High	None noted.
Silver-haired Bat	Generally Associated	Feeds	Low	None noted.
Snowshoe Hare	Generally Associated	Feeds and Breeds	High	None noted.
Striped Skunk	Generally Associated	Feeds and Breeds	Moderate	None noted.
Townsend's Big-eared Bat	Generally Associated	Feeds	Moderate	None noted.
Townsend's Chipmunk	Generally Associated	Feeds and Breeds	High	None noted.
Townsend's Mole	Generally Associated	Feeds and Breeds	High	None noted.
Townsend's Vole	Generally Associated	Feeds and Breeds	High	None noted.

Mammals Associated with Westside Riparian - Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Trowbridge's Shrew	Generally Associated	Feeds and Breeds	High	None noted.
Virginia Opossum	Generally Associated	Feeds and Breeds	Low	None noted.
Western Red-backed Vole	Generally Associated	Feeds and Breeds	High	None noted.
Western Spotted Skunk	Generally Associated	Feeds and Breeds	Low	None noted.
American Marten	Present	Feeds and Breeds	Moderate	None noted.
Brazilian Free-tailed Bat	Present	Feeds	Moderate	None noted.
Bushy-tailed Woodrat	Present	Feeds and Breeds	Moderate	None noted.
Heather Vole	Present	Feeds and Breeds	Moderate	None noted.
Masked Shrew	Present	Feeds and Breeds	Moderate	None noted.
Montane Shrew	Present	Feeds and Breeds	Moderate	None noted.
Red Tree Vole	Present	Feeds and Breeds	Moderate	None noted.
Vagrant Shrew	Present	Feeds and Breeds	Moderate	None noted.

Reptiles Associated with Westside Riparian - Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Common Garter Snake	Closely Associated	Feeds and Breeds	High	None noted.
Western Pond Turtle	Closely Associated	Feeds and Breeds	High	None noted.
Northern Alligator Lizard	Generally Associated	Feeds and Breeds	High	None noted.
Northwestern Garter Snake	Generally Associated	Feeds and Breeds	High	None noted.
Pacific Coast Aquatic Garter Snake	Generally Associated	Feeds and Breeds	High	None noted.
Painted Turtle	Generally Associated	Feeds and Breeds	Moderate	None noted.
Red-eared Slider Turtle	Generally Associated	Feeds and Breeds	Moderate	None noted.

Reptiles Associated with Westside Riparian - Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Rubber Boa	Generally Associated	Feeds and Breeds	High	Usually does not occur far from water.
Sharptail Snake	Generally Associated	Feeds and Breeds	Moderate	None noted.
Snapping Turtle	Generally Associated	Feeds and Breeds	Moderate	Avoids flowing water that lacks vegetation.
Western Rattlesnake	Generally Associated	Feeds and Breeds	High	None noted.
Western Terrestrial Garter Snake	Generally Associated	Feeds and Breeds	High	None noted.
California Mountain Kingsnake	Present	Feeds and Breeds	Moderate	None noted.
Common Kingsnake	Present	Feeds and Breeds	Low	None noted.
Ringneck Snake	Present	Feeds and Breeds	Moderate	None noted.
Southern Alligator Lizard	Present	Feeds and Breeds	Moderate	None noted.

Wildlife Species Found in Montane Coniferous Wetlands

Amphibians Associated with Montane Coniferous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Long-toed Salamander	Closely Associated	Feeds and Breeds	High	Rare or absent where predatory fish are occur. Requires ponds, shallow lake edges, seasonal pools (like elk wallows) or slow streams for breeding.
Northwestern Salamander	Closely Associated	Feeds and Breeds	High	Requires ponds or stream backwaters for breeding.
Pacific Chorus (Tree) Frog	Closely Associated	Feeds and Breeds	High	Requires ponds, seasonal pools, temporary rain-filled depressions or slow streams for breeding.
Rough-skinned Newt	Closely Associated	Feeds and Breeds	High	Requires ponds or stream backwaters with abundant aquatic vegetation for breeding.
Western Toad	Closely Associated	Feeds and Breeds	High	None noted.
Cascades Frog	Generally Associated	Feeds and Breeds	High	Requires bogs or ponds with cold springs for breeding.
Columbia Spotted Frog	Generally Associated	Feeds and Breeds	Moderate	Rare or absent where predatory fish or bullfrogs occur. Requires shallow water in wet meadows or stream/pond edges with abundant aquatic vegetation for breeding.
Oregon Spotted Frog	Present	Feeds and Breeds	High	Rare or absent where predatory fish or bullfrogs occur. Requires shallow water in wet meadows or stream/pond edges with abundant aquatic vegetation for breeding.
Pacific Giant Salamander	Present	Feeds and Breeds	High	Requires small to mid-sized streams with a streambed of gravel, boulders and large logs for breeding.
Red-legged Frog	Present	Feeds and Breeds	High	Requires cool-water ponds, lake edges or slow streams for breeding.

Birds Associated with Montane Coniferous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Bufflehead	Closely Associated	Feeds and Breeds	Moderate	Nests in tree cavities.
Evening Grosbeak	Closely Associated	Feeds and Breeds	Moderate	None noted.
American Robin	Generally Associated	Feeds and Breeds	High	None noted.
Barrow's Goldeneye	Generally Associated	Feeds and Breeds	Moderate	Nests in tree cavities.
Black Swift	Generally Associated	Feeds	Low	Black swifts are long-distance foragers that may travel many miles from breeding sites and take advantage of flying insects caught in updrafts over just about any habitat.
Black-backed Woodpecker	Generally Associated	Feeds and Breeds	Moderate	Reach highest densities in recently burned forests or areas of bark beetle infestations.
Blue Grouse	Generally Associated	Feeds and Breeds	Moderate	None noted.
Bohemian Waxwing	Generally Associated	Feeds	Moderate	There are a few confirmed records of breeding. Nesting habitat usually is beaver ponds and bog areas.
Boreal Chickadee	Generally Associated	Feeds and Breeds	Low	None noted.
Brown Creeper	Generally Associated	Feeds and Breeds	Moderate	None noted.
Calliope Hummingbird	Generally Associated	Feeds and Breeds	Moderate	None noted.
Cassin's Finch	Generally Associated	Feeds and Breeds	High	None noted.
Cedar Waxwing	Generally Associated	Feeds and Breeds	Moderate	None noted.
Chestnut-backed Chickadee	Generally Associated	Feeds and Breeds	Moderate	None noted.
Common Nighthawk	Generally Associated	Feeds	Moderate	None noted.
Common Raven	Generally Associated	Feeds and Breeds	High	None noted.
Common Redpoll	Generally Associated	Feeds	Moderate	None noted.
Cooper's Hawk	Generally Associated	Feeds and Breeds	High	None noted.
Dark-eyed Junco	Generally Associated	Feeds and Breeds	High	None noted.

Birds Associated with Montane Coniferous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Dusky Flycatcher	Generally Associated	Feeds and Breeds	Moderate	None noted.
Golden-crowned Kinglet	Generally Associated	Feeds and Breeds	High	None noted.
Gray Jay	Generally Associated	Feeds and Breeds	High	None noted.
Great Gray Owl	Generally Associated	Feeds and Breeds	High	None noted.
Hairy Woodpecker	Generally Associated	Feeds and Breeds	Moderate	None noted.
Hermit Thrush	Generally Associated	Feeds and Breeds	High	None noted.
Hermit Warbler	Generally Associated	Feeds and Breeds	Moderate	None noted.
Macgillivray's Warbler	Generally Associated	Feeds and Breeds	High	None noted.
Mountain Chickadee	Generally Associated	Feeds and Breeds	Moderate	None noted.
Nashville Warbler	Generally Associated	Feeds and Breeds	Moderate	None noted.
Northern Flicker	Generally Associated	Feeds and Breeds	Moderate	None noted.
Northern Goshawk	Generally Associated	Feeds and Breeds	High	None noted.
Northern Pygmy-owl	Generally Associated	Feeds and Breeds	Low	None noted.
Northern Saw-whet Owl	Generally Associated	Feeds and Breeds	Moderate	None noted.
Olive-sided Flycatcher	Generally Associated	Feeds and Breeds	Moderate	None noted.
Pacific-slope Flycatcher	Generally Associated	Feeds and Breeds	Moderate	None noted.
Peregrine Falcon	Generally Associated	Feeds	High	None noted.
Pileated Woodpecker	Generally Associated	Feeds and Breeds	Moderate	None noted.
Pine Grosbeak	Generally Associated	Feeds and Breeds	Moderate	None noted.
Pine Siskin	Generally Associated	Feeds and Breeds	High	None noted.
Red Crossbill	Generally Associated	Feeds and Breeds	Moderate	None noted.

Birds Associated with Montane Coniferous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Red-breasted Nuthatch	Generally Associated	Feeds and Breeds	Moderate	None noted.
Red-breasted Sapsucker	Generally Associated	Feeds and Breeds	Moderate	None noted.
Ruby-crowned Kinglet	Generally Associated	Feeds and Breeds	High	None noted.
Ruffed Grouse	Generally Associated	Feeds and Breeds	Moderate	None noted.
Rufous Hummingbird	Generally Associated	Feeds and Breeds	Moderate	None noted.
Song Sparrow	Generally Associated	Feeds and Breeds	Moderate	None noted.
Spruce Grouse	Generally Associated	Feeds and Breeds	High	Uses this habitat where adjacent to lodgepole alpine forest.
Steller's Jay	Generally Associated	Feeds and Breeds	Moderate	None noted.
Swainson's Thrush	Generally Associated	Feeds and Breeds	High	None noted.
Three-toed Woodpecker	Generally Associated	Feeds and Breeds	Moderate	Reach highest densities in recently burned forests or areas of bark beetle infestations.
Townsend's Warbler	Generally Associated	Feeds and Breeds	Moderate	None noted.
Tree Swallow	Generally Associated	Feeds and Breeds	Moderate	Requires snags not far from open water for nesting.
Varied Thrush	Generally Associated	Feeds and Breeds	Moderate	None noted.
Vaux's Swift	Generally Associated	Feeds and Breeds	Moderate	None noted.
Violet-green Swallow	Generally Associated	Feeds and Breeds	Moderate	None noted.
Warbling Vireo	Generally Associated	Feeds and Breeds	Low	None noted.
Western Tanager	Generally Associated	Feeds and Breeds	Moderate	None noted.
Williamson's Sapsucker	Generally Associated	Feeds and Breeds	Low	None noted.
Willow Flycatcher	Generally Associated	Feeds and Breeds	Moderate	None noted.
Wilson's Warbler	Generally Associated	Feeds and Breeds	High	None noted.

Birds Associated with Montane Coniferous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Winter Wren	Generally Associated	Feeds and Breeds	Moderate	None noted.
Yellow-rumped Warbler	Generally Associated	Feeds and Breeds	Moderate	None noted.
American Crow	Present	Feeds and Breeds	High	None noted.
American Kestrel	Present	Feeds and Breeds	Moderate	None noted.
Barn Swallow	Present	Feeds and Breeds	Moderate	Can nest anywhere buildings, bridges, or overhanging cliffs occur in close proximity to water.
Brown-headed Cowbird	Present	Feeds and Breeds	Moderate	None noted.
Chipping Sparrow	Present	Feeds and Breeds	Low	None noted.
Clark's Nutcracker	Present	Feeds	Low	None noted.
European Starling	Present	Feeds and Breeds	Low	Requires snags or trees with cavities or buildings with crevices for nesting. Most likely to use this habitat where adjacent to agriculture or urban habitats.
Great Horned Owl	Present	Feeds and Breeds	High	None noted.
Merlin	Present	Feeds	Low	None noted.
Mountain Bluebird	Present	Feeds and Breeds	Moderate	None noted.
Northern Rough-winged Swallow	Present	Feeds	Moderate	Requires burrows in dirt banks, usually next to water, for nesting.
Turkey Vulture	Present	Feeds and Breeds	Low	Requires rocky outcrops, small caves, boulder piles, ledges on high cliffs or large hollow logs for nesting.
Western Screech-owl	Present	Feeds and Breeds	Moderate	None noted.
White-winged Crossbill	Present	Feeds and Breeds	Moderate	None noted.
Wood Duck	Present	Feeds and Breeds	Moderate	Nests in tree cavities.

Mammals Associated with Montane Coniferous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Big Brown Bat	Closely Associated	Feeds and Breeds	High	Requires snags, caves, mines, rock crevices, or bridges for breeding and roosting.
Deer Mouse	Closely Associated	Feeds and Breeds	High	None noted.
Long-tailed Vole	Closely Associated	Feeds and Breeds	High	None noted.
Pacific Jumping Mouse	Closely Associated	Feeds and Breeds	High	None noted.
Snowshoe Hare	Closely Associated	Feeds and Breeds	High	None noted.
Southern Red-backed Vole	Closely Associated	Feeds and Breeds	High	None noted.
Water Shrew	Closely Associated	Feeds and Breeds	High	Lead a semi-aquatic life and require cold, clear water in small streams or ponds with abundant cover in the form of rocks, overhanging banks, etc.
Water Vole	Closely Associated	Feeds and Breeds	Low	None noted.
Yuma Myotis	Closely Associated	Feeds and Breeds	High	More closely associated with water than other bat species. Uses caves, mines, loose bark and bark crevices typically close to water.
American Beaver	Generally Associated	Feeds and Breeds	High	None noted.
American Marten	Generally Associated	Feeds and Breeds	Moderate	None noted.
Black Bear	Generally Associated	Feeds and Breeds	High	None noted.
Black-tailed Deer	Generally Associated	Feeds and Breeds	High	None noted.
Bobcat	Generally Associated	Feeds	Moderate	None noted.
Bushy-tailed Woodrat	Generally Associated	Feeds and Breeds	Moderate	None noted.
California Myotis	Generally Associated	Feeds and Breeds	High	Uses rock crevices, hollow trees, mines or caves for breeding.
Columbian Ground Squirrel	Generally Associated	Feeds and Breeds	Moderate	None noted.
Columbian Mouse	Generally Associated	Feeds and Breeds	High	None noted.

Mammals Associated with Montane Coniferous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Common Porcupine	Generally Associated	Feeds and Breeds	Moderate	None noted.
Coyote	Generally Associated	Feeds and Breeds	High	None noted.
Creeping Vole	Generally Associated	Feeds and Breeds	High	None noted.
Fisher	Generally Associated	Feeds and Breeds	Low	None noted.
Golden-mantled Ground Squirrel	Generally Associated	Feeds and Breeds	Moderate	None noted.
Hoary Bat	Generally Associated	Feeds	Low	Requires trees for roosting, but forages in openings and at edges of forests.
Little Brown Myotis	Generally Associated	Feeds	High	Uses caves, mines, or hollow trees, often near water.
Long-eared Myotis	Generally Associated	Feeds and Breeds	Moderate	Uses caves, mines, hollow trees, loose bark or rock crevices.
Long-tailed Weasel	Generally Associated	Feeds and Breeds	Moderate	None noted.
Mink	Generally Associated	Feeds and Breeds	Moderate	None noted.
Montane Vole	Generally Associated	Feeds and Breeds	High	None noted.
Moose	Generally Associated	Feeds and Breeds	Moderate	None noted.
Mountain Caribou	Generally Associated	Feeds and Breeds	High	None noted.
Mountain Lion	Generally Associated	Feeds	High	None noted.
Mule Deer	Generally Associated	Feeds and Breeds	High	None noted.
Northern Bog Lemming	Generally Associated	Feeds and Breeds	Moderate	None noted.
Northern Flying Squirrel	Generally Associated	Feeds and Breeds	High	None noted.
Northern Pocket Gopher	Generally Associated	Feeds and Breeds	Moderate	None noted.
Pacific Water Shrew	Generally Associated	Feeds and Breeds	High	Closely tied to water.
Rocky Mountain Elk	Generally Associated	Feeds and Breeds	High	None noted.

Mammals Associated with Montane Coniferous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Roosevelt Elk	Generally Associated	Feeds and Breeds	High	None noted.
Shrew-mole	Generally Associated	Feeds and Breeds	High	None noted.
Silver-haired Bat	Generally Associated	Feeds and Breeds	Moderate	Uses trees, bark crevices, and snags for summer roosts; if present in winter, may use caves, mines, or rock crevices for hibernacula.
Townsend's Big-eared Bat	Generally Associated	Feeds	Moderate	None noted.
Townsend's Chipmunk	Generally Associated	Feeds and Breeds	High	None noted.
Trowbridge's Shrew	Generally Associated	Feeds and Breeds	High	None noted.
Western Jumping Mouse	Generally Associated	Feeds and Breeds	Moderate	None noted.
Western Spotted Skunk	Generally Associated	Feeds and Breeds	Low	None noted.
Wolverine	Generally Associated	Feeds and Breeds	Low	None noted.
Coast Mole	Present	Feeds and Breeds	Moderate	None noted.
Ermine	Present	Feeds and Breeds	Low	None noted.
Fringed Myotis	Present	Feeds	Low	Requires caves, mines or rock crevices.
Grizzly Bear	Present	Feeds	Moderate	None noted.
Heather Vole	Present	Feeds and Breeds	Moderate	None noted.
Long-legged Myotis	Present	Feeds and Breeds	Moderate	Uses caves or mines as hibernacula. Uses hollow trees, loose bark or rock crevices for maternity colonies.
Lynx	Present	Feeds	Low	None noted.
Masked Shrew	Present	Feeds and Breeds	Moderate	None noted.
Montane Shrew	Present	Feeds and Breeds	Low	None noted.
Vagrant Shrew	Present	Feeds and Breeds	Moderate	None noted.

Reptiles Associated with Montane Coniferous Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Common Garter Snake	Closely Associated	Feeds and Breeds	Moderate	None noted.
Rubber Boa	Generally Associated	Feeds and Breeds	High	Usually does not occur far from water.

Wildlife Species Found in Eastside (Interior) Riparian -Wetlands

Amphibians Associated with Eastside (Interior) Riparian - Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Bullfrog	Closely Associated	Feeds and Breeds	High	Requires warm-water ponds, marshes, or river/stream backwaters for breeding.
Columbia Spotted Frog	Closely Associated	Feeds and Breeds	High	Rare or absent where predatory fish or bullfrogs occur. Requires shallow water in wet meadows or stream/pond edges with abundant aquatic vegetation for breeding.
Great Basin Spadefoot	Closely Associated	Feeds and Breeds	High	Requires ponds or temporary rain-filled depressions for breeding.
Long-toed Salamander	Closely Associated	Feeds and Breeds	High	Rare or absent where predatory fish are occur. Requires ponds, shallow lake edges, seasonal pools (like elk wallows) or slow streams for breeding.
Northern Leopard Frog	Closely Associated	Feeds and Breeds	High	Requires ponds or lake edges with dense aquatic and emergent vegetation for breeding.
Pacific Chorus (Tree) Frog	Closely Associated	Feeds and Breeds	High	Requires ponds, seasonal pools, temporary rain-filled depressions or slow streams for breeding.
Tailed Frog	Closely Associated	Feeds and Breeds	Moderate	Requires clear, cold steep-gradient streams for breeding.
Tiger Salamander	Closely Associated	Feeds and Breeds	High	Rare or absent where predatory fish occur. Requires warm ponds or shallow lake edges for breeding.
Western Toad	Closely Associated	Feeds and Breeds	High	None noted.
Woodhouse's Toad	Closely Associated	Feeds and Breeds	High	Requires warm, shallow water in ponds, lakes, or slow streams for breeding.
Cascades Frog	Generally Associated	Feeds and Breeds	Moderate	Requires bogs or ponds with cold springs for breeding.
Northwestern Salamander	Present	Feeds and Breeds	High	Range extends only peripherally into the eastside Cascades in Washington only. Requires ponds or stream backwaters for breeding.
Red-legged Frog	Present	Feeds and Breeds	High	Range extends only peripherally into the eastside Cascades.

Amphibians Associated with Eastside (Interior) Riparian - Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Rough-skinned Newt	Present	Feeds and Breeds	High	Range doesn't extend very far east of Cascades. Needs ponds/backwaters & profuse aquatic vegetation breed.

Birds Associated with Eastside (Interior) Riparian -Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
American Black Duck	Closely Associated	Feeds and Breeds	Low	None noted.
American Dipper	Closely Associated	Feeds and Breeds	High	None noted.
American Redstart	Closely Associated	Feeds and Breeds	High	None noted.
Bank Swallow	Closely Associated	Feeds and Breeds	High	Requires burrows in dirt banks, usually next to water, for nesting.
Barn Swallow	Closely Associated	Feeds and Breeds	High	Can nest anywhere buildings, bridges, or overhanging cliffs occur in close proximity to water.
Belted Kingfisher	Closely Associated	Feeds and Breeds	High	None noted.
Black-billed Magpie	Closely Associated	Feeds and Breeds	High	None noted.
Black-crowned Night-heron	Closely Associated	Feeds and Breeds	High	Occur in wide bottomlands, not narrow canyons.
Blue Grouse	Closely Associated	Feeds and Breeds	High	None noted.
Bullock's Oriole	Closely Associated	Feeds and Breeds	Moderate	None noted.
Cedar Waxwing	Closely Associated	Feeds and Breeds	High	None noted.
Cliff Swallow	Closely Associated	Feeds and Breeds	Moderate	Can nest anywhere rimrock, overhanging cliffs, buildings or bridges occur in close proximity to water.
Common Merganser	Closely Associated	Feeds and Breeds	High	Nests in tree cavities near large lakes or rivers.
Common Yellowthroat	Closely Associated	Feeds and Breeds	High	None noted.
Cordilleran Flycatcher	Closely Associated	Feeds and Breeds	Moderate	None noted.
Double-crested Cormorant	Closely Associated	Feeds and Breeds	High	None noted.

Birds Associated with Eastside (Interior) Riparian -Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
European Starling	Closely Associated	Feeds and Breeds	High	Requires snags or trees with cavities or buildings with crevices for nesting. Most likely to use this habitat where adjacent to agriculture or urban habitats.
Fox Sparrow	Closely Associated	Feeds and Breeds	High	None noted.
Gray Catbird	Closely Associated	Feeds and Breeds	High	None noted.
Great Blue Heron	Closely Associated	Feeds and Breeds	High	None noted.
Great Egret	Closely Associated	Feeds and Breeds	High	More common in broad flood plains; does not occur in narrow riparian corridors as a breeder.
Harlequin Duck	Closely Associated	Feeds and Breeds	High	None noted.
Hooded Merganser	Closely Associated	Feeds and Breeds	Moderate	Nests in tree cavities.
Lazuli Bunting	Closely Associated	Feeds and Breeds	High	None noted.
Lincoln's Sparrow	Closely Associated	Feeds and Breeds	Moderate	None noted.
Long-eared Owl	Closely Associated	Feeds and Breeds	High	Typically nests in the abandoned nests of other corvids, raptors or squirrels.
Mallard	Closely Associated	Feeds and Breeds	High	None noted.
Mourning Dove	Closely Associated	Feeds and Breeds	High	None noted.
Northern Rough-winged Swallow	Closely Associated	Feeds and Breeds	High	Requires burrows in dirt banks, usually next to water, for nesting.
Northern Waterthrush	Closely Associated	Feeds and Breeds	High	None noted.
Pygmy Nuthatch	Closely Associated	Feeds and Breeds	Moderate	Uses this habitat where ponderosa pine occurs.
Red-eyed Vireo	Closely Associated	Feeds and Breeds	Moderate	Range of red-eyed vireo overlaps that of large black cottonwood groves.
Red-naped Sapsucker	Closely Associated	Feeds and Breeds	High	None noted.
Ring-necked Pheasant	Closely Associated	Feeds and Breeds	High	None noted.

Birds Associated with Eastside (Interior) Riparian -Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Ruffed Grouse	Closely Associated	Feeds and Breeds	High	None noted.
Sharp-tailed Grouse	Closely Associated	Feeds	High	In Oregon this was historically very important overwintering habitat.
Snowy Egret	Closely Associated	Feeds and Breeds	High	Requires tall shrubs or trees for nesting.
Solitary Sandpiper	Closely Associated	Feeds	Moderate	None noted.
Spotted Sandpiper	Closely Associated	Feeds and Breeds	Moderate	None noted.
Tree Swallow	Closely Associated	Feeds and Breeds	Moderate	Requires snags not far from open water for nesting.
Veery	Closely Associated	Feeds and Breeds	High	None noted.
Warbling Vireo	Closely Associated	Feeds and Breeds	High	None noted.
Western Screech-owl	Closely Associated	Feeds and Breeds	High	None noted.
Willow Flycatcher	Closely Associated	Feeds and Breeds	Moderate	None noted.
Wood Duck	Closely Associated	Feeds and Breeds	High	Nests in tree cavities.
Yellow Warbler	Closely Associated	Feeds and Breeds	High	None noted.
Yellow-billed Cuckoo	Closely Associated	Feeds and Breeds	Moderate	Not known from eastside Washington (even historically); in Oregon species may still occur in a few scattered locations.
Yellow-breasted Chat	Closely Associated	Feeds and Breeds	Moderate	None noted.
American Crow	Generally Associated	Feeds and Breeds	High	None noted.
American Goldfinch	Generally Associated	Feeds and Breeds	High	None noted.
American Kestrel	Generally Associated	Feeds and Breeds	High	None noted.
American Robin	Generally Associated	Feeds and Breeds	High	None noted.
American Tree Sparrow	Generally Associated	Feeds	Moderate	None noted.
Bald Eagle	Generally Associated	Feeds and Breeds	High	None noted.

Birds Associated with Eastside (Interior) Riparian -Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Barn Owl	Generally Associated	Feeds and Breeds	High	Requires cliffs, caves, rimrock, or tree cavities for nesting.
Black Swift	Generally Associated	Feeds and Breeds	Low	Requires suitable cliffs behind waterfalls for breeding.
Black-capped Chickadee	Generally Associated	Feeds and Breeds	Moderate	None noted.
Black-chinned Hummingbird	Generally Associated	Feeds and Breeds	Low	None noted.
Black-headed Grosbeak	Generally Associated	Feeds and Breeds	High	None noted.
Black-throated Gray Warbler	Generally Associated	Feeds and Breeds	Low	None noted.
Bobolink	Generally Associated	Feeds and Breeds	Moderate	None noted.
Bohemian Waxwing	Generally Associated	Feeds	Moderate	None noted.
Brewer's Blackbird	Generally Associated	Feeds and Breeds	Moderate	None noted.
Broad-tailed Hummingbird	Generally Associated	Feeds and Breeds	Low	High elevation, montane riparian. Breeding suspected but not confirmed. Birds have been found in eastside riparian aspen and willow habitats.
Brown Creeper	Generally Associated	Feeds and Breeds	Moderate	None noted.
Brown-headed Cowbird	Generally Associated	Feeds and Breeds	High	None noted.
Bufflehead	Generally Associated	Feeds and Breeds	Moderate	Nests in tree cavities.
Bushtit	Generally Associated	Feeds and Breeds	Moderate	None noted.
California Quail	Generally Associated	Feeds and Breeds	High	Uses this habitat where adjacent to more open habitats.
Calliope Hummingbird	Generally Associated	Feeds and Breeds	Moderate	None noted.
Canyon Wren	Generally Associated	Feeds and Breeds	Moderate	Requires rocky outcrops, cliffs for nesting.
Cassin's Finch	Generally Associated	Feeds and Breeds	High	None noted.
Cassin's Vireo	Generally Associated	Feeds and Breeds	Moderate	None noted.

Birds Associated with Eastside (Interior) Riparian -Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Cattle Egret	Generally Associated	Feeds and Breeds	High	Requires shrubs or trees for nesting.
Chipping Sparrow	Generally Associated	Feeds and Breeds	Moderate	None noted.
Common Nighthawk	Generally Associated	Feeds	Moderate	None noted.
Common Raven	Generally Associated	Feeds and Breeds	High	None noted.
Common Redpoll	Generally Associated	Feeds	Moderate	None noted.
Cooper's Hawk	Generally Associated	Feeds and Breeds	High	None noted.
Dark-eyed Junco	Generally Associated	Feeds and Breeds	High	None noted.
Downy Woodpecker	Generally Associated	Feeds and Breeds	Moderate	None noted.
Dusky Flycatcher	Generally Associated	Feeds and Breeds	Moderate	None noted.
Eastern Kingbird	Generally Associated	Feeds and Breeds	Moderate	Requires groves of hardwoods for breeding.
Evening Grosbeak	Generally Associated	Feeds and Breeds	Moderate	None noted.
Flammulated Owl	Generally Associated	Feeds and Breeds	Moderate	Must have ponderosa pine/aspen.
Golden Eagle	Generally Associated	Feeds and Breeds	High	Needs cliffs for nesting.
Golden-crowned Kinglet	Generally Associated	Feeds and Breeds	Moderate	None noted.
Golden-crowned Sparrow	Generally Associated	Feeds	Moderate	None noted.
Gray Jay	Generally Associated	Feeds and Breeds	Moderate	None noted.
Great Horned Owl	Generally Associated	Feeds and Breeds	High	None noted.
Greater Yellowlegs	Generally Associated	Feeds	Low	None noted.
Green-winged Teal	Generally Associated	Feeds	High	None noted.
Hairy Woodpecker	Generally Associated	Feeds and Breeds	Moderate	None noted.

Birds Associated with Eastside (Interior) Riparian -Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Hermit Thrush	Generally Associated	Feeds and Breeds	High	None noted.
House Wren	Generally Associated	Feeds and Breeds	Moderate	None noted.
Killdeer	Generally Associated	Feeds and Breeds	Moderate	None noted.
Least Flycatcher	Generally Associated	Feeds and Breeds	Low	Has bred regularly at Clyde Holiday State Wayside, Grant County, Oregon, and numerous singing males have been found in eastside hardwood riparian habitats in Washington.
Lesser Yellowlegs	Generally Associated	Feeds	Low	None noted.
Lewis's Woodpecker	Generally Associated	Feeds and Breeds	Moderate	None noted.
Macgillivray's Warbler	Generally Associated	Feeds and Breeds	High	None noted.
Mountain Bluebird	Generally Associated	Feeds and Breeds	Moderate	None noted.
Mountain Chickadee	Generally Associated	Feeds and Breeds	Moderate	None noted.
Mountain Quail	Generally Associated	Feeds and Breeds	High	None noted.
Nashville Warbler	Generally Associated	Feeds and Breeds	High	None noted.
Northern Flicker	Generally Associated	Feeds and Breeds	Moderate	None noted.
Northern Goshawk	Generally Associated	Feeds and Breeds	High	None noted.
Northern Pygmy-owl	Generally Associated	Feeds and Breeds	High	None noted.
Olive-sided Flycatcher	Generally Associated	Feeds and Breeds	Moderate	None noted.
Orange-crowned Warbler	Generally Associated	Feeds and Breeds	High	None noted.
Osprey	Generally Associated	Feeds and Breeds	High	None noted.
Peregrine Falcon	Generally Associated	Feeds and Breeds	High	Needs cliffs for nesting.
Pied-billed Grebe	Generally Associated	Feeds and Breeds	High	None noted.

Birds Associated with Eastside (Interior) Riparian -Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Pileated Woodpecker	Generally Associated	Feeds and Breeds	Moderate	None noted.
Pine Siskin	Generally Associated	Feeds and Breeds	High	None noted.
Red-breasted Nuthatch	Generally Associated	Feeds and Breeds	Moderate	None noted.
Red-breasted Sapsucker	Generally Associated	Feeds and Breeds	Moderate	Only in south-central Oregon: may hybridize with Red-naped sapsucker in Eastside riparian.
Red-tailed Hawk	Generally Associated	Feeds and Breeds	High	None noted.
Red-winged Blackbird	Generally Associated	Feeds and Breeds	High	None noted.
Ring-necked Duck	Generally Associated	Feeds and Breeds	High	None noted.
Rufous Hummingbird	Generally Associated	Feeds and Breeds	Moderate	None noted.
Sandhill Crane	Generally Associated	Feeds and Breeds	High	Uses open riparian areas with only scattered willows or willow clumps.
Savannah Sparrow	Generally Associated	Feeds and Breeds	Moderate	None noted.
Say's Phoebe	Generally Associated	Feeds and Breeds	Moderate	Needs cliffs or rimrock for nesting.
Song Sparrow	Generally Associated	Feeds and Breeds	High	None noted.
Spotted Towhee	Generally Associated	Feeds and Breeds	Moderate	None noted.
Steller's Jay	Generally Associated	Feeds and Breeds	Moderate	None noted.
Swainson's Hawk	Generally Associated	Feeds and Breeds	High	None noted.
Swainson's Thrush	Generally Associated	Feeds and Breeds	High	None noted.
Townsend's Solitaire	Generally Associated	Feeds	Moderate	None noted.
Turkey Vulture	Generally Associated	Feeds and Breeds	High	Requires rocky outcrops, small caves, boulder piles, ledges on high cliffs or large hollow logs for nesting.
Violet-green Swallow	Generally Associated	Feeds and Breeds	Moderate	None noted.

Birds Associated with Eastside (Interior) Riparian -Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Western Bluebird	Generally Associated	Feeds and Breeds	High	None noted.
Western Tanager	Generally Associated	Feeds and Breeds	Moderate	None noted.
Western Wood-pewee	Generally Associated	Feeds and Breeds	Moderate	None noted.
White-breasted Nuthatch	Generally Associated	Feeds and Breeds	Moderate	Uses this habitat where ponderosa pine and hardwoods occur in the riparian zone.
White-crowned Sparrow	Generally Associated	Feeds and Breeds	High	None noted.
White-headed Woodpecker	Generally Associated	Feeds and Breeds	Low	Requires a ponderosa pine component.
White-throated Swift	Generally Associated	Feeds	Low	May use riparian areas as travel corridors.
Wild Turkey	Generally Associated	Feeds and Breeds	High	None noted.
Williamson's Sapsucker	Generally Associated	Feeds and Breeds	Low	None noted.
Wilson's Warbler	Generally Associated	Feeds and Breeds	High	None noted.
Winter Wren	Generally Associated	Feeds and Breeds	Moderate	None noted.
Yellow-rumped Warbler	Generally Associated	Feeds and Breeds	Moderate	None noted.
American Wigeon	Present	Feeds	Moderate	None noted.
Ash-throated Flycatcher	Present	Feeds and Breeds	Low	None noted.
Band-tailed Pigeon	Present	Feeds	Moderate	None noted.
Barred Owl	Present	Feeds and Breeds	Moderate	None noted.
Black-backed Woodpecker	Present	Feeds and Breeds	Moderate	None noted.
Canada Goose	Present	Feeds and Breeds	Moderate	None noted.
Chukar	Present	Feeds	Moderate	None noted.
Green-tailed Towhee	Present	Feeds and Breeds	Moderate	None noted.
House Finch	Present	Feeds and Breeds	Moderate	Uses this habitat where it is not too far from urban or agricultural areas.

Birds Associated with Eastside (Interior) Riparian -Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Lesser Goldfinch	Present	Feeds and Breeds	Moderate	None noted.
Merlin	Present	Feeds	Low	None noted.
Northern Harrier	Present	Feeds and Breeds	High	None noted.
Northern Saw-whet Owl	Present	Feeds and Breeds	Low	None noted.
Prairie Falcon	Present	Feeds and Breeds	High	Needs cliffs for nesting.
Red Crossbill	Present	Feeds	Low	None noted.
Rough-legged Hawk	Present	Feeds	High	None noted.
Ruby-crowned Kinglet	Present	Feeds and Breeds	Moderate	None noted.
Three-toed Woodpecker	Present	Feeds and Breeds	Moderate	None noted.
Townsend's Warbler	Present	Feeds and Breeds	Low	Heavy use during migration, and occasional breeding where conifers are present.
Vaux's Swift	Present	Feeds and Breeds	Low	None noted.

Mammals Associated with Eastside (Interior) Riparian -Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
American Beaver	Closely Associated	Feeds and Breeds	High	None noted.
Big Brown Bat	Closely Associated	Feeds and Breeds	High	Requires snags, caves, mines, rock crevices, or bridges for breeding and roosting.
Bushy-tailed Woodrat	Closely Associated	Feeds and Breeds	High	None noted.
Deer Mouse	Closely Associated	Feeds and Breeds	High	None noted.
Long-legged Myotis	Closely Associated	Feeds and Breeds	Moderate	Uses caves or mines as hibernacula. Uses hollow trees, loose bark or rock crevices for maternity colonies.
Long-tailed Vole	Closely Associated	Feeds and Breeds	High	None noted.
Meadow Vole	Closely Associated	Feeds and Breeds	Low	None noted.
Mink	Closely Associated	Feeds and Breeds	Moderate	None noted.

Mammals Associated with Eastside (Interior) Riparian -Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Muskrat	Closely Associated	Feeds and Breeds	Moderate	None noted.
Northern River Otter	Closely Associated	Feeds and Breeds	High	None noted.
Pacific Jumping Mouse	Closely Associated	Feeds and Breeds	High	None noted.
Pallid Bat	Closely Associated	Feeds and Breeds	Moderate	Requires rock cliffs, caves or mines for breeding.
Raccoon	Closely Associated	Feeds and Breeds	Moderate	None noted.
Snowshoe Hare	Closely Associated	Feeds and Breeds	High	None noted.
Southern Red-backed Vole	Closely Associated	Feeds and Breeds	High	None noted.
Water Shrew	Closely Associated	Feeds and Breeds	High	Lead a semi-aquatic life and require cold, clear water in small streams or ponds with abundant cover in the form of rocks, overhanging banks, etc.
Water Vole	Closely Associated	Feeds and Breeds	Low	None noted.
Western Harvest Mouse	Closely Associated	Feeds and Breeds	High	None noted.
Western Jumping Mouse	Closely Associated	Feeds and Breeds	High	None noted.
Western Pipistrelle	Closely Associated	Feeds and Breeds	High	Requires cliffs, rimrock, caves or mines for breeding and roosting.
Western Small-footed Myotis	Closely Associated	Feeds and Breeds	Moderate	Requires cliffs, rimrock, boulders, or talus for breeding.
White-tailed Deer (Eastside)	Closely Associated	Feeds and Breeds	High	None noted.
Yuma Myotis	Closely Associated	Feeds and Breeds	High	More closely associated with water than other bat species. Uses caves, mines, loose bark and bark crevices typically close to water.
Black Bear	Generally Associated	Feeds and Breeds	High	None noted.
Black-tailed Deer	Generally Associated	Feeds and Breeds	High	None noted.
Bobcat	Generally Associated	Feeds and Breeds	Moderate	None noted.
Broad-footed Mole	Generally Associated	Feeds and Breeds	Moderate	None noted.

Mammals Associated with Eastside (Interior) Riparian -Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Brush Rabbit	Generally Associated	Feeds and Breeds	Moderate	None noted.
California Myotis	Generally Associated	Feeds and Breeds	High	Uses rock crevices, hollow trees, mines or caves for breeding.
Columbian Ground Squirrel	Generally Associated	Feeds and Breeds	Moderate	None noted.
Columbian Mouse	Generally Associated	Feeds and Breeds	Moderate	None noted.
Common Porcupine	Generally Associated	Feeds and Breeds	Moderate	None noted.
Coyote	Generally Associated	Feeds and Breeds	High	None noted.
Creeping Vole	Generally Associated	Feeds and Breeds	High	None noted.
Eastern Cottontail	Generally Associated	Feeds and Breeds	Low	Likely uses this habitat where adjacent to urban or agricultural habitats.
Eastern Fox Squirrel	Generally Associated	Feeds and Breeds	Moderate	None noted.
Ermine	Generally Associated	Feeds and Breeds	Low	None noted.
Feral Horse	Generally Associated	Feeds	Low	None noted.
Feral Pig	Generally Associated	Feeds and Breeds	Moderate	None noted.
Fisher	Generally Associated	Feeds and Breeds	Low	None noted.
Fringed Myotis	Generally Associated	Feeds and Breeds	Low	Requires caves, mines or rock crevices.
Hoary Bat	Generally Associated	Feeds	Moderate	Requires trees for roosting, but forages in openings and at edges of forests.
Little Brown Myotis	Generally Associated	Feeds and Breeds	High	Uses caves, mines, or hollow trees, often near water.
Long-eared Myotis	Generally Associated	Feeds and Breeds	Moderate	Uses caves, mines, hollow trees, loose bark or rock crevices.
Long-tailed Weasel	Generally Associated	Feeds and Breeds	Moderate	None noted.
Masked Shrew	Generally Associated	Feeds and Breeds	High	None noted.
Montane Vole	Generally Associated	Feeds and Breeds	High	None noted.

Mammals Associated with Eastside (Interior) Riparian -Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Moose	Generally Associated	Feeds and Breeds	High	None noted.
Mountain Caribou	Generally Associated	Feeds and Breeds	High	None noted.
Mountain Lion	Generally Associated	Feeds and Breeds	High	None noted.
Mule Deer	Generally Associated	Feeds and Breeds	High	None noted.
Northern Flying Squirrel	Generally Associated	Feeds and Breeds	High	None noted.
Northern Pocket Gopher	Generally Associated	Feeds and Breeds	Moderate	None noted.
Pacific Water Shrew	Generally Associated	Feeds and Breeds	Moderate	Closely tied to water.
Red Fox	Generally Associated	Feeds and Breeds	Low	Non-native Red fox.
Rocky Mountain Elk	Generally Associated	Feeds and Breeds	High	None noted.
Shrew-mole	Generally Associated	Feeds and Breeds	High	None noted.
Silver-haired Bat	Generally Associated	Feeds and Breeds	Moderate	Uses trees, bark crevices, and snags for summer roosts; if present in winter, may use caves, mines, or rock crevices for hibernacula.
Spotted Bat	Generally Associated	Feeds and Breeds	Moderate	Requires clliffs for breeding.
Striped Skunk	Generally Associated	Feeds and Breeds	Moderate	None noted.
Townsend's Big-eared Bat	Generally Associated	Feeds	Moderate	None noted.
Trowbridge's Shrew	Generally Associated	Feeds and Breeds	High	None noted.
Virginia Opossum	Generally Associated	Feeds and Breeds	Low	None noted.
Western Spotted Skunk	Generally Associated	Feeds and Breeds	Low	None noted.
Wild Burro	Generally Associated	Feeds	Low	None noted.
Yellow-bellied Marmot	Generally Associated	Feeds and Breeds	Moderate	Requires talus slopes, lava fields, rimrock, or boulder fields in close proximity to grassy openings or meadows.

Mammals Associated with Eastside (Interior) Riparian -Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Yellow-pine Chipmunk	Generally Associated	Feeds and Breeds	Moderate	None noted.
American Badger	Present	Feeds	Moderate	None noted.
American Marten	Present	Feeds and Breeds	Moderate	None noted.
Coast Mole	Present	Feeds and Breeds	Moderate	None noted.
Golden-mantled Ground Squirrel	Present	Feeds and Breeds	Moderate	None noted.
Grizzly Bear	Present	Feeds	Moderate	None noted.
Heather Vole	Present	Feeds and Breeds	Moderate	None noted.
Least Chipmunk	Present	Feeds and Breeds	Low	None noted.
Montane Shrew	Present	Feeds and Breeds	Moderate	None noted.
Preble's Shrew	Present	Feeds and Breeds	Low	None noted.
Pronghorn Antelope	Present	Feeds	Moderate	None noted.
Vagrant Shrew	Present	Feeds and Breeds	Moderate	None noted.
White-tailed Jackrabbit	Present	Feeds and Breeds	Moderate	None noted.

Reptiles Associated with Eastside (Interior) Riparian-Wetlands				
Species (alphabetically by common name within each association)	**Association**	**Activity**	**Confidence**	**Comments**
Common Garter Snake	Closely Associated	Feeds and Breeds	High	None noted.
Gopher Snake	Generally Associated	Feeds and Breeds	High	None noted.
Northern Alligator Lizard	Generally Associated	Feeds and Breeds	High	None noted.
Painted Turtle	Generally Associated	Feeds and Breeds	Moderate	None noted.
Racer	Generally Associated	Feeds and Breeds	High	None noted.
Rubber Boa	Generally Associated	Feeds and Breeds	High	Usually does not occur far from water.
Sharptail Snake	Generally Associated	Feeds and Breeds	Moderate	None noted.
Western Rattlesnake	Generally Associated	Feeds and Breeds	High	None noted.
Western Terrestrial Garter Snake	Generally Associated	Feeds and Breeds	High	None noted.
Southern Alligator Lizard	Present	Feeds and Breeds	Low	None noted.

Appendix C – FEMA Flood Study Update Maps (2026)

1. INTRODUCTION

With the passage of the Growth Management Act (GMA), local jurisdictions throughout Washington State, including City of Walla Walla (City), were required to develop policies and regulations to designate and protect critical areas. The GMA and the Revised Code of Washington (RCW) 36.70A.030(11) define critical areas as wetlands, fish and wildlife habitat conservation areas, frequently flooded areas, critical aquifer recharge areas, and geologically hazardous areas. The GMA requires local jurisdictions to periodically review and evaluate their adopted policies and regulations regarding critical areas.

City of Walla Walla adopted the most recent critical areas ordinance (CAO) in 2019. According to the Washington Administrative Code (WAC) 365-195-915, critical area regulations must incorporate best available science (BAS), and any deviations from science-based recommendations must be identified, assessed, and explained. In addition, jurisdictions must give special consideration to conservation or protection measures necessary to preserve or enhance anadromous fisheries. A BAS review for this code update has been prepared as a separate document (Facet 2026).

City of Walla Walla's critical areas ordinance is codified in Chapter 21.04 of the City of Walla Walla's Municipal Code (WWMC). This gap analysis reviews the current critical areas regulations and evaluates gaps in consistency between them and BAS or the GMA. It also includes recommendations for improvements to general aspects of the CAO, such as clarity, consistency, and ease of use. The primary intention of this gap analysis is to help guide the update of the City's critical areas policies and regulations.

1.1 Report Structure

Sections 2 through 7 provide recommendations for updating the City's existing critical areas regulations. Section 2 addresses the general provisions applicable to all critical areas; Sections 3 through 7 address the different types of critical areas covered by the GMA, organized according to their organization in the current code. Each section contains a summary table of recommendations followed by a detailed analysis of the existing code, potential gaps, and recommendations.

2. GENERAL PROVISIONS (WWMC 21.04.005-21.04.140)

This section addresses provisions applicable to all types of critical areas as described in WWMC 21.04.005-21.04.140. Table 1 summarizes the recommended updates.

Table 1. General Provisions review summary.

Code Section	Title	Review Comment and Recommendations	Reason for Recommendation
21.04.005	Purpose	Add No Net Loss and special consideration for anadromous fish	Consistency
21.04.010	Authority	No comments or suggestions	
21.04.015	Applicability	Make Figure 1 more legible or remove it.	Legibility
21.04.020	Definitions	1. Add all critical area definitions consistent with the WAC. 2. Review critical area designations against definitions.	1. Clarity 2. Consistency
21.04.025	Severability	No comments or suggestions	
21.04.030	Jurisdiction – Critical areas	No comments or suggestions	
21.04.035	Critical area maps	Ensure maps are updated accordingly.	Clarity
21.04.040	Best available science	No comments or suggestions	
21.04.045	Administrative procedures	No comments or suggestions	
21.04.050	Fees	No comments or suggestions	
21.04.055	Administrative rules	No comments or suggestions	
21.04.060	Permit processing	No comments or suggestions	
21.04.065	Appeals	No comments or suggestions	
21.04.070	Interpretation	No comments or suggestions	
21.04.075	Relationship to other regulations	No comments or suggestions	
21.04.080	Multiple designations	No comments or suggestions	
21.04.085	Allowed activities	No comments or suggestions	
21.04.090	Reasonable use	1. Note: CAR by a qualified professional is required. 2. Consider adding details to clarify what constitutes reasonable use.	1. BAS 2. Consistency

Code Section	Title	Review Comment and Recommendations	Reason for Recommendation
21.04.095	Critical area reports – General requirements	No comments or suggestions	
21.04.100	Critical area reports – Modifications to requirements	No comments or suggestions	
21.04.105	Mitigation requirements	Review and update language for consistency with the 2008 Federal Mitigation Rule hierarchy	Administrative consistency
21.04.110	Mitigation sequencing	No comments or suggestions	
21.04.115	Mitigation plan requirements	Consider adding requirements for timing, legal protections, and use of native plant species	BAS, clarity
21.04.120	Bonds to ensure mitigation, maintenance and monitoring	No comments or suggestions	
21.04.125	Notice on title	No comments or suggestions	
21.04.130	Building setbacks	Review width requirement	BAS
21.04.135	Critical area inspections	No comments or suggestions	
21.04.140	Unauthorized critical area alterations and enforcement	No comments or suggestions	

2.1 Purpose (21.04.005)

WCC 21.04.005.E: We recommend incorporating the following statements to align with WAC 365-190-080: "to protect all functions and values of critical areas to ensure no net loss of ecological functions and values," and "to give special consideration to conservation or protection measures necessary to preserve or enhance anadromous fisheries."

2.2 Applicability (21.04.015)

Figure 1 under WWMC 21.04.015.C is low resolution and difficult to read. Update for better legibility or remove from code.

2.3 Definitions (21.04.020)

We recommend aligning the critical area definitions more closely with WAC 365-190-030 to ensure consistency with state standards. Definitions of critical areas should reflect those provided in the WAC, and all applicable critical area definitions should be provided within the definitions section for clarity and consistency. Additional designation criteria is provided in each critical area code section. Designation information may be incorporated into definitions as appropriate.

Best available science (BAS)

Consider removing text, "'Citations of Recommended Sources of Best Available Science for Designating and Protecting Critical Areas' published by the state Office of Community Development." The broader definition of BAS in the WAC allows use of current information that meets BAS standards.

Critical Aquifer Recharge Areas

Recommend updating to align with WAC 365-190-100, which is more detailed than WAC 365-190-030(2).

Erosion hazard areas

Recommend adding general statement from WAC to WWMC definition as shown in underlined text below.

WAC definition: *"Erosion hazard areas" are those areas containing soils which, according to the United States Department of Agriculture Natural Resources Conservation Service Soil Survey Program, may experience significant erosion. Erosion hazard areas also include coastal erosion-prone areas and channel migration zones.*

WWMC definition: "*Erosion hazard areas*" *— means at least those areas identified by the United States Department of Agriculture National Resources Conservation Service as ~~having a~~ prone to significant erosion, including severe rill and inter-rill erosion hazard.*

Frequently flooded areas

WWMC 21.04.020 does not currently include a definition for Frequently Flooded Areas. It is recommended that this term be defined consistent with WAC 365-190-030(8) and incorporated into the definitions section for clarity and regulatory consistency.

WAC definition: "*Frequently flooded areas*" *are lands in the flood plain subject to at least a one percent or greater chance of flooding in any given year, or within areas subject to flooding due to high groundwater. These areas include, but are not limited to, streams, rivers, lakes, coastal areas, wetlands, and areas where high groundwater forms ponds on the ground surface.*

Geologically hazardous areas

The City's definition of geologically hazardous areas is consistent with the WAC. Development types could be added to match the WAC if preferred.

WAC definition: "*Geologically hazardous areas*" *are areas that because of their susceptibility to erosion, sliding, earthquake, or other geological events, are not suited to siting commercial, residential, or industrial development consistent with public health or safety concerns.*

WWMC definition: "*Geologically hazardous areas*" *— means areas that may not be suited to development consistent with public health, safety or environmental standards because of their susceptibility to erosion, sliding, earthquake, or other geological events as designated by WAC 365-190-030(9). Types of geologically hazardous areas include: erosion, landslide, seismic, mine, and volcanic hazards.*

Groundwater

A portion of the groundwater definition in the WAC 173-100-040 is missing. Recommend adding.

Landslide hazard areas

WAC 365-190-120(6) provides greater detail than the currently referenced definition under WAC 365-190-030(10). Recommend updating to provide more detail.

Water Typing System

Since water types F, Np and Ns are no used to assign stream buffer widths, they are not referenced in WWC 21.04.650 and do not need to be defined.

Wetland Category

Update to reference the current 2014 Ecology Wetland Rating System for Eastern Washington.

Wetlands

Recommend removing delineation methodology from the wetland definition as shown in the strike-through below.

WAC definition: "*Wetland*" *or* "*wetlands*" *means areas that are inundated or saturated by surface water or groundwater at a frequency and duration sufficient to support, and that under normal circumstances do support, a prevalence of vegetation typically adapted for life in saturated soil conditions. Wetlands generally include swamps, marshes, bogs, and similar areas. Wetlands do not include those artificial wetlands intentionally created from nonwetland sites, grass-lined swales, canals, detention facilities, wastewater treatment facilities, farm ponds, and landscape amenities, or those wetlands created after July 1, 1990, that were unintentionally created as a result of the construction of a road, street, or highway.*

However, wetlands may include those artificial wetlands intentionally created from nonwetland areas to mitigate conversion of wetlands, if permitted by the County or City.

WWMC definition: "*Wetlands" — means those areas that are inundated or saturated by surface or ground water at a frequency and duration sufficient to support, and that under normal circumstances do support, a prevalence of vegetation adapted for life in saturated soil conditions. Wetlands generally include swamps, marshes, bogs and similar areas. Wetlands do not include those artificial wetlands intentionally created from nonwetland sites, including, but not limited to, irrigation and drainage ditches, grass-lined swales, canals, detention facilities, wastewater treatment facilities, farm ponds, and landscape amenities, or those wetlands created after July 1, 1990, that were unintentionally created as a result of the construction of a road, street, or highway. Wetlands may include those artificial wetlands intentionally created from nonwetland areas to mitigate the conversion of wetlands. ~~For identifying and delineating a wetland, local government shall use the approved federal delineation manual and regional supplement, as amended.~~*

2.4 Critical Area Maps (21.04.035)

WWMC states critical area maps "*will be updated as inventories are completed in compliance with the requirements of the Growth Management Act, and additional maps may be added as appropriate.*" However, the City's critical area maps are not readily accessible through its online resources.

We recommend that the City update all critical area maps with any new data available and that these maps be made easily accessible through the City's website to improve transparency and usability.

2.5 Allowed activities (21.04.085)

For clarity, recommend stating in introductory paragraph that allowed activities are still subject to underlaying permit or approval and must be consistent with this chapter. Any new critical area impacts/modification is subject to mitigation sequencing requirements.

City staff noted that property fencing is a recurring issue not adequately addressed in the current code. Recommend adding language to the allowed activities section to provide direction on fencing used in landscaping, farming, and property line marking capacities.

2.6 Reasonable Use (21.04.090)

We recommend noting a critical areas report prepared by a qualified professional must be provided to support the Director's review of reasonable use exception criteria.

Consider adding additional criteria to standardize reasonable use reviews, such as square footage limits and/or neighborhood analyses. This can help standardize the review process for both city staff and applicants.

2.7 Mitigation Requirements (21.04.105)

Review this code section regarding mitigation banking against the 2008 Federal Mitigation Rule hierarch (Ecology publication #21-06-003 excerpt below for reference). Cities commonly prefer to keep mitigation within city limits. However, when state and federal permits apply, the city may add code language to allow the federally required mitigation approach. Recommend incorporating language to allow off-site mitigation when it is required by other agencies, state or federal, and is demonstrated by support watershed health.

Federal Mitigation Rule hierarchy

The 2008 Federal Mitigation Rule (33 CFR Part 332.3[b] and 40 CFR Part 230.93[b]) lists the preference of mitigation options in the following order.

1. Mitigation bank credits
2. In-lieu fee program credits
3. Permittee-responsible mitigation under a watershed approach
4. Permittee-responsible mitigation through on-site and in-kind mitigation
5. Permittee-responsible mitigation through off-site and/or out-of-kind mitigation

2.8 Mitigation Plan Requirements (21.04.115)

This code section could add additional mitigation plan and plan sheet requirements from Ecology's sample wetland regulations (Ecology publication 22-06-014, Appendix A). Since these requirements apply to all critical areas, only general requirements would be applicable. This may include requirements to:

1) Describe the proposed timing of impact and mitigation activities, and

2) Proof the mitigation area and any associated buffers are protected by a legal mechanism such as a critical areas tract, conservation easement, and/or Notice on Title.

It is considered best management practice for restoration activities to use native plant species appropriate to the site for revegetation of disturbed or degraded areas. Incorporating locally adapted native plant species also supports resilience to climate change by improving the ability of wetlands to withstand environmental stressors. While it is likely the policy is being applied in practice, the current mitigation requirements do not explicitly mandate the use of native species. The City may choose to incorporate this requirement into code to ensure consistency and strengthen long-term ecological outcomes.

2.9 Building setback (21.04.130)

Currently, a five-foot building setback is required from the edge of all critical area buffers. The intent of the setback is to allow maintenance of a structure without encroaching into protected critical area buffers. The City may consider increasing the standard building setback to fifteen feet and allowing reduction down to five feet when the applicant demonstrates long-term building maintenance can be achieved without encroaching upon the critical area buffer. The City may choose to set a higher standard building setback value and allow reductions through the critical areas report process.

3. CRITICAL AQUIFER RECHARGE AREAS (WWMC 21.04.200-260)

Table 2. Critical Aquifer Recharge Areas review summary.

Code Section	Title	Review Comment and Recommendations	Reason for Recommendation
21.04.200	Critical aquifer recharge areas – Designation	Update to match Ecology guidance	Clarity
21.04.210	Mapping of critical aquifer recharge areas	Update *Critical Area Map 1: CARA* reference	Clarity
21.04.220	Activities allowed in critical aquifer recharge areas	Add specifications to reduce impacts	Clarification
21.04.230	Critical area report – Additional requirements for critical aquifer recharge areas.	Add mitigation plan / measures to critical area report requirements	BAS
21.04.240	Performance standards – General requirements	No comments or suggestions	
21.04.250	Performance standards – Specific uses	No comments or suggestions	
21.04.260	Uses prohibited in critical aquifer recharge areas	Consider adding a table with additional details	Clarification

3.1 Critical aquifer recharge areas—Designation (21.04.200)

The Washington State Department of Ecology (Ecology) has revised the Critical Aquifer Recharge Area Guidance. The current guidance is *2021 Critical Aquifer Recharge Areas: Guidance Document* (Pub 05-10-028).[1] We recommend adding "current or as revised" when referring to this document.

[1] 2021 Critical Aquifer Recharge Areas: Guidance Document

Also update CARA map reference for consistency with WWMC 21.04.210.

3.2 Mapping of critical aquifer recharge areas (21.04.210)

The map referenced by name in the code (WWMC 21.04.210.A), *Critical Area Map 1: Critical aquifer recharge areas*, was not readily found. Recommend revising the language to more generally reference publicly available CARA maps. Retain provision B (WWMC 21.04.210.B), stating that public CARA maps are advisory, as-is.

3.3 Activities allowed in critical aquifer recharge areas (21.04.220)

Recommend the City add a reference to RCW 90.48 (Water Pollution Control) to ensure consistency with applicable state requirements.

Additionally, the City may impose conditions of approval, as necessary, to prevent groundwater degradation. Such conditions should be based on established prevention, control, and treatment methods, including BAS. Where applicable, all proposals must also comply with water source protection requirements and guidance provided by the Federal Environmental Protection Agency, the Washington State Department of Ecology, the Washington State Department of Health, and the Walla Walla County Health Department. Groundwater quantity and quality protection standards could be located under the performance standards subsection (WWMC 21.04.240).

3.4 Critical Area Report—Additional requirements for critical aquifer recharge areas (21.04.230)

Documentation showing best management practices (BMPs) are implemented or a mitigation plan may be required to address groundwater impacts identified in the hydrogeologic site evaluation, including monitoring, process controls, remediation, and discussion of alternatives. Appropriate BMPs and mitigation measures should be applied. Process needs to ensure that soil analysis for infiltration BMPs is in accordance with (Storm Water Management Model (SWMM) measures to prevent delivery of contaminants to groundwater.

3.5 Uses prohibited in critical aquifer recharge areas (21.04.260)

Currently this code section is similar to Walla Walla County 'Uses prohibited in critical aquifer recharge areas' code. Consider adding 'dry wells on sites used for vehicle repair and servicing or dry cleaners' as stated in Walla Walla County code WWCMC 18.08.260). Recommend retaining general provision 'F' to cover other impactful land uses not listed.

Alternatively, the City could add a table to list prohibited uses by CARA classification. For example, a hazardous liquid transmission pipeline may be prohibited in a Class 1 (1- and 5-Year Wellhead Protection Area) but allowed in Class 2 and 3 CARA when state and federal standards are met.

4. WETLANDS (WWMC 21.04.300-350)

Table 3. Wetlands review summary.

Code Section	Title	Review Comment and Recommendations	Reason for Recommendation
21.04.300	Wetlands critical areas – Designation	Minor descriptive edit recommended to simplify	Clarity
21.04.310	Mapping of wetland areas	Update *Critical Area Map 2: Wetlands* reference	Clarity
21.04.320	Critical area report – Additional requirements for wetland areas	Check study area width against final wetland buffer widths; update as needed to capture widest buffer.	BAS
21.04.330	Activities allowed in wetlands.	No comments or suggestions	
21.04.340	Performance standards – General requirements	1. Consider adding further detail on disconnected buffers. 2. Add vegetation standards criteria 3. Add GPS option 4. Add small wetland exemption	1. Clarity 2. BAS / clarity 3. BAS / clarity 4. BAS
21.04.341	Signs and fencing of wetlands.	No comments or suggestions	
21.04.342	Performance standards – Wetland buffer averaging	No comments or suggestions	
21.04.343	Performance standards – Wetland buffer increase	No comments or suggestions	
21.04.344	Performance standards – Wetland buffer decrease.	Deletion recommended	BAS
21.04.345	Performance standards – Buffer management plan.	Review for redundancy with general mitigation requirements	Clarity
21.04.346	Performance standards – Specific activities and uses.	1. Passive recreation – consider adding ADA allowance. 2. Stormwater facilities – discourage single-point discharge	1. Administration 2. BAS

Code Section	Title	Review Comment and Recommendations	Reason for Recommendation
21.04.347	Performance standards – Mitigation requirements	Review simplified table (Ecology 2022 recommendations)	BAS / Administration
21.04.348	Performance standards – Wetland mitigation plan	No comments or suggestions	
21.04.350	Wetland mitigation banks	No comments or suggestions	

4.1 Wetland critical areas – Designation (21.04.300)

Generally, the designation and rating descriptions align with best practices and Ecology guidance. Recommend simplifying the 'Category I Wetland' description to align with the level of detail provided in the other category descriptions.

4.2 Mapping of wetlands (21.04.310)

The map referenced by name in the code (WWMC 21.04.310.A), *Critical Area Map 2: Wetlands*, was not readily found. Recommend revising the language to more generally reference publicly available wetland maps. Retain provision B (WWMC 21.04.310.B), stating that public wetland maps are advisory, as-is.

4.3 Critical areas report – Additional requirements for wetland areas (21.04.320)

Since the widest wetland buffer under current City code is 250-feet, recommend updating the distance stated under WWMC 21.04.320.B.3 from 200-feet to 250-feet.

4.4 Performance standards – General requirements (21.04.340)

Disconnected buffers (WWMC 21.04.340.C.2)

Additional detail on what constitutes a significant development is provided in Ecology's Sample Wetland Regulations (Publication # 22-06-014, Appendix A). This information could be added for clarity. An excerpt from Ecology's sample wetland regulations is below:

> *Functionally Disconnected Buffer Area. Buffers may exclude areas that are functionally and effectively disconnected from the wetland by an existing public or private road or legally established development, as determined by the [Administrator]. Functionally and effectively disconnected means that the road or other significant development blocks the protective measures provided by a buffer.*

Significant developments shall include built public infrastructure such as roads and railroads, and private developments such as homes or commercial structures. The [Administrator] shall evaluate whether the interruption will affect the entirety of the buffer. Individual structures may not fully interrupt buffer function. In such cases, the allowable buffer exclusion should be limited in scope to just the portion of the buffer that is affected. Where questions exist regarding whether a development functionally disconnects the buffer, or the extent of that impact, the [Administrator] may require a critical area report to analyze and document the buffer functionality.

Examples of how this guidance has been incorporated into wetland buffer regulations are provided below.

Walla Walla County, in addition to incorporating Ecology's sample regulation language above for specific uses and activities under WWCMC 18.08.345.H, states the following under performance standard - general requirements (WWCMC 18.08.340.C.2):

Buffers shall not include areas that are functionally and effectively disconnected from the wetland by a road or other substantially developed surface of sufficient width and with use characteristics such that buffer functions are not provided.

Skagit County draft code update, words this disconnected buffer provision as follows (SCC 14.24.230.6).

(6) Where a legally established and constructed public roadway, private roads, and legally established development as determined by the Director functionally disconnects a wetland buffer as demonstrated in a critical area report, the Director may approve a modification of the standard buffer width to the edge of the development, provided:

(a) The isolated part of the buffer does not provide additional protection of the wetland; and

(b) The isolated part of the buffer provides insignificant biological, geological, or hydrological buffer functions relating to the wetland; and

(c) If the resulting buffer distance is less than 75% of the standard or optional buffer for the applicable wetland category, no further reduction will be allowed.

(d) The legally established development includes hard surfaces a minimum of 20 feet wide that completely isolates the project area from the critical area.

Standard buffer widths (WWMC 21.04.340.C.3)

City code currently requires applicants to restore or rehabilitate disturbed vegetation within the buffer with native plant communities. The City may include an option to apply a wider buffer if vegetation conditions are not brought up to standards. Additionally, the City may consider adding a clear description of what a native plant community represents, such as density or coverage requirements.

Measurement of Wetland buffers (WWMC 21.04.340.C.4)

Consider adding Ecology recommended language to allow GPS-mapping (Publication # 22-06-014, Appendix A).

> *Wetland delineations will be documented on a ground-verified map using either professional surveying methods or an equivalent professional method using GPS with sub-meter accuracy.*

Table 4: Recommended buffer widths

The current City-required buffers are based on Ecology's 2018 buffer guidance (Appendix 8-C) and are consistent with BAS.

Although Ecology's 2018 guidance is part of the BAS-based guidance available, Ecology updated buffer recommendations in 2022 to include additional clarity surrounding buffer table options. The underlying science behind buffer width recommendations in the 2018 and 2022 publications remains the same. Ecology's 2022 buffer recommendations outlines a preferred option (Publication # 22-06-014, Appendix D, Option 1) that includes consideration of a habitat corridor for wetlands with moderate to high habitat scores. This option also requires minimization measures to be applied, or buffer width increased. See Appendix A of this report for both the 2018 and 2022 Ecology wetland buffer guidance.

Small wetlands exemption (*Not Applicable)*

The small wetlands exemption in 2022 Ecology sample (Ecology Publication #22-06-014, Appendix A) does not apply to ecoregions that use the Arid West Regional Supplement (US Army Corps 2008). Ecology guidance states that wetlands in the arid west perform functions at an 'outsized role due to their rarity in the landscape.' Therefore, this is not applicable to small wetlands in the City of Walla Walla.

4.5 Performance standards – Wetland buffer decrease (21.04.344)

Ecology guidance no longer supports outright wetland buffer reductions. Other regulatory mechanisms, such as reasonable use exceptions or function buffer interruptions, may be used to apply lower buffers. If the City continues to apply Ecology's 2018 wetland buffer guidance, then buffer reductions would be limited to guidance on reducing the intensity of impacts from proposed land uses. See Ecology Publication #05-06-008, July 2018 revision excerpt below (8C.2.4).

8C.2.4 Special Conditions for a Possible Reduction in Buffer Widths

8C.2.4.1 Condition 1: Reduction in Buffer Width Based on Reducing the Intensity of Impacts from Proposed Land Uses

The buffer widths recommended for proposed land uses with high-intensity impacts to wetlands can be reduced to those recommended for moderate-intensity impacts under the following conditions:

- For wetlands that score moderate or high for habitat (6 points or more for the habitat functions), the width of the buffer can be reduced if both of the following criteria are met:

  1) A relatively undisturbed, vegetated corridor at least 100-feet wide is protected between the wetland and any other Priority Habitats as defined by the Washington State Department of Fish and Wildlife. The latest definitions of priority habitats and their locations are available on the WDFW web site at: http://wdfw.wa.gov/hab/phshabs.htm)

     The corridor must be protected for the entire distance between the wetland and the Priority Habitat by some type of legal protection such as a conservation easement.

  2) Measures to minimize the impacts of different land uses on wetlands, such as the examples summarized in Table 8C-8, are applied.

- For wetlands that score less than 6 points for habitat, the buffer width can be reduced to that required for moderate land-use impacts by applying measures to minimize the impacts of the proposed land uses (see examples in Table 8C-8).

Table 8C-8. Examples of measures to minimize impacts to wetlands from proposed change in land use that have high impacts. (This is not a complete list of measures.)

Examples of Disturbance	Activities and Uses that Cause Disturbances	Examples of Measures to Minimize Impacts
Lights	• Parking lots • Warehouses • Manufacturing • Residential	• Direct lights away from wetland
Noise	• Manufacturing • Residential	• Locate activity that generates noise away from wetland
Toxic runoff*	• Parking lots • Roads • Manufacturing • Residential areas • Application of agricultural pesticides • Landscaping	• Route all new, untreated runoff away from wetland while ensuring wetland is not dewatered • Establish covenants limiting use of pesticides within 150 ft of wetland • Apply integrated pest management
Stormwater runoff	• Parking lots • Roads • Manufacturing • Residential areas • Commercial • Landscaping	• Retrofit stormwater detention and treatment for roads and existing adjacent development • Prevent channelized flow from lawns that directly enters the buffer
Change in water regime	• Impermeable surfaces • Lawns • Tilling	• Infiltrate or treat, detain, and disperse into buffer new runoff from impervious surfaces and new lawns
Pets and human disturbance	• Residential areas	• Use privacy fencing; plant dense vegetation to delineate buffer edge and to discourage disturbance using vegetation appropriate for the ecoregion; place wetland and its buffer in a separate tract
Dust	• Tilled fields	• Use best management practices to control dust
* These examples are not necessarily adequate for minimizing toxic runoff if threatened or endangered species are present at the site.		

8C.2.4.2 Condition 2: Reductions in Buffer Widths Where Existing Roads or Structures Lie Within the Buffer

Where a legally established, non-conforming use of the buffer exists (e.g., a road or structure that lies within the width of buffer recommended for that wetland), proposed actions in the buffer may be permitted as long as they do not increase the degree of non-conformity. This means no increase in the impacts to the wetland from activities in the buffer.

For example, if a land use with high impacts (e.g., building an urban road) is being proposed next to a Category II wetland with a moderate level of function for habitat, a 150-foot buffer would be needed to protect functions (see Table 8C-6). If, however, an existing urban road is already present and only 50 feet from the edge of the Category II wetland, the additional 100 feet of buffer may not be needed if the road is being widened. A vegetated buffer on the other side of the road would not help buffer the existing impacts to the wetland from the road. If the existing road is resurfaced or widened (e.g., to add a sidewalk) along the upland edge, without any further roadside development that would increase the degree of non-conformity, the additional buffer is not necessary. The associated increase in impervious surface from widening a road, however, may necessitate mitigation for impacts from stormwater.

If, however, the proposal is to build a new development (e.g., shopping center) along the upland side of the road, the impacts to the wetland and its functions may increase. This would increase the degree of non-conformity. The project proponent would need to provide the additional 100 feet of buffer extending beyond the road or apply buffer averaging (see Section 8C.2.6).

8C.2.4.3 Condition 3: Reduction in Buffer Widths Through an Individual Rural Stewardship Plan

A Rural Stewardship Plan (RSP) is the product of a collaborative effort between rural property owners and a local government to tailor a management plan specific for a rural parcel of land. The goal of the RSP is better management of wetlands than what would be achieved through strict adherence to regulations. In exchange, the landowner gains flexibility in the widths of buffers required, in clearing limits, and in other requirements found in the regulations. For example, dense development in rural residential areas can be treated as having a low level of impact when the development of the site is managed through a locally approved RSP. The voluntary agreement includes provisions for restoration, maintenance, and long-term monitoring and specifies the widths of buffers needed to protect each wetland within the RSP.

4.6 Performance standards – Buffer management plan (21.04.345)

Review and consider if this is beneficial or redundant with mitigation requirements under WWMC 21.04.105 – 115. For example, maintaining dense native plant cover, keeping invasive plant cover low, and requiring five years of monitoring and maintenance are covered in the general mitigation code sections. Mitigation plans are required to propose mitigation consistent with BAS and include a planting plan with species and density (WWMC 21.04.115). WWMC 21.04.105.F states mitigation monitoring shall be required for five years and a monitoring program is required under WWMC 21.04.115.D.

One unique detail under WWMC 21.04.345 is the reference to 'Table 8, Walla Walla County Conservation District native riparian vegetation planting guidelines'. That document was not located in brief online search. Recommend a more general reference to incorporating BAS since specific resources can change over time.

4.7 Performance standards – Specific activities and uses (21.04.346)

Passive recreation (21.04.346.B.1) limits trails to a five-foot width. Consider adding an allowance for wider trails when necessary for ADA compliance.

Stormwater facilities (21.04.346.C) may also note that a single-discharge point should be avoided. Dispersed discharges allow the buffer to provide infiltration and water quality functions over the distance remaining.

4.8 Performance standards – Mitigation requirements (21.04.347)

Table 5: Mitigation ratios for Eastern Washington is from the 2018 Ecology guidance. The 2022 Ecology guidance (Publication # 22-06-014, Appendix E) offers a simplified version of this table. Review and consider adopting (Appendix B of this report). Please note, both 2018 and 2022 options are both considered BAS.

4.9 Performance standards – Wetland mitigation plan (21.04.348)

Recommend additional text to reference Ecology's requirement to select wetland mitigation sites using a watershed approach (Publication #10-06-007). This would align City requirements with state and federal mitigation requirements.

5. MAPPING OF FREQUENTLY FLOODED AREAS (WWMC 21.04.400)

Table 4. Frequently Flooded Areas Review Summary.

Code Section	Title	Review Comment and Recommendations	Reason for Recommendation
21.04.400 *(new)*	Frequently flooded areas – designation	Add critical area designation	Compliance
21.04.~~400~~10	Mapping of Frequently Flooded Areas	Update map reference	Clarity
21.04.420 *(new)*	Frequently flooded areas- regulation	Add regulation	Compliance

The City may choose to make the updates suggested below or remove this content from Chapter 21.04 and reference Chapter 21.10. This would simplify the code.

5.1 FFA Mapping-Commerce Guidelines (21.04.400-420)

5.1.1 Frequently Flooded Areas Designation (21.04.400 NEW)

It is recommended to designate frequently flooded areas are designated in the critical area ordinance to ensure compliance with state regulations. [WAC 365-190-110]

5.1.2 Mapping of Frequently Flooded Areas (21.04.410 NEW #)

The map referenced by name in the code (WWMC 21.04.400.A), *Critical Area Map 3: Frequently Flooded Areas*, was not readily found. Recommend revising the language to more generally reference publicly available FFA maps. Retain provision B (WWMC 21.04.410.B), stating that public flood hazard maps are advisory, as-is.

5.1.3 Frequently Flooded Areas Regulation (21.04.420 NEW)

Title 15 (Buildings and Construction) and Chapter 21.10 (Floodplain Management) of the City of Walla Walla Code regulate proposed activities adjacent to or within frequently flooded areas. If allowed, any structure permitted in these flood areas, it is subject to the flood-proofing regulations provided in Title 15 and Chapter 21.10.

Many other communities in Washington take a similar approach and regulate areas of special flood hazards using National Flood Insurance Program standards, deeming this sufficient for their frequently flooded areas codes (Commerce 2023). Commerce notes that this approach can meet the minimum requirements without exceptional circumstances. However, Commerce also notes that FEMA maps do

not address all community flood risk and that the frequently flooded area designation should be based on BAS. Commerce, therefore, encourages local governments to consider additional flood risks in their communities and address related regulatory issues in their frequently flooded areas. Ecology invites local governments to exceed FEMA minimum requirements for floodplain management (Ecology n.d.).

FEMA recently completed a flood study updated for Walla Walla County. This includes risk assessment mapping. Those updated maps are included in Appendix C of this report for City reference.

6. GEOLOGICALLY HAZARDOUS AREAS (WWMC 21.04.500-21.04.560)

Table 5. Geologically Hazardous Areas review summary.

Code Section	Title	Review Comment and Recommendations	Reason for Recommendation
21.04.500	Geologically hazardous areas – Designation	Review definitions	Consistency with WAC
21.04.510	Mapping of geologically hazardous areas	Update *Critical Area Map 4: Geologic Hazard Areas* reference	Clarity
21.04.520	Activities allowed in geologically hazardous areas.	No comments or suggestions	
21.04.530	Critical area report – Additional requirements for geologically hazardous areas.	No comments or suggestions	
21.04.540	Critical area report – Additional requirements for specific geologically hazardous areas	No comments or suggestions	
21.04.550	Performance standards – General Requirements	No comments or suggestions	
21.04.560	Performance standards – Specific hazards	No comments or suggestions	

6.1 Geologically hazardous areas—Designation (21.04.500)

The Walla Walla Municipal Code does not mirror the Washington Administrative Code designations verbatim; however, it generally aligns with the intent and underlying definitions, and in some cases provides greater specificity and detail.

We recommend conducting a comprehensive review of the WAC definitions for all hazard areas to determine whether revisions to the WWMC definitions and/or designations are warranted to ensure consistency and regulatory clarity. WAC 365-190-120 defines Geologically Hazardous Areas as follows:

(1) Geologically hazardous areas include areas susceptible to erosion, sliding, earthquake, or other geological events. They pose a threat to the health and safety of citizens when incompatible commercial, residential, or industrial development is sited in areas of significant hazard.

(2) Some geological hazards can be reduced or mitigated by engineering, design, or modified construction or mining practices so that risks to public health and safety are minimized. When technology cannot reduce risks to acceptable levels, building in geologically hazardous areas must be avoided. The distinction between avoidance and compensatory mitigation should be considered by counties and cities that do not currently classify geological hazards, as they develop their classification scheme.

(3) Areas that are susceptible to one or more of the following types of hazards shall be classified as a geologically hazardous area:

(a) Erosion hazard;

(b) Landslide hazard;

(c) Seismic hazard; or

(d) Areas subject to other geological events such as coal mine hazards and volcanic hazards including: Mass wasting, debris flows, rock falls, and differential settlement.

(4) Counties and cities should assess the risks and classify geologically hazardous areas as either:

(a) Known or suspected risk;

(b) No known risk; or

(c) Risk unknown - data are not available to determine the presence or absence of risk.

(5) Erosion hazard areas include areas likely to become unstable, such as bluffs, steep slopes, and areas with unconsolidated soils. Erosion hazard areas may also include coastal erosion areas: This information can be found in the Washington state coastal atlas available from the department of ecology. Counties and cities may consult with the United States Department of Agriculture Natural Resources Conservation Service for data to help identify erosion hazard areas.

(6) Landslide hazard areas include areas subject to landslides based on a combination of geologic, topographic, and hydrologic factors. They include any areas susceptible to landslide because of any combination of bedrock, soil, slope (gradient), slope aspect, structure, hydrology, or other factors, and include, at a minimum, the following:

(a) Areas of historic failures, such as:

(i) Those areas delineated by the United States Department of Agriculture Natural Resources Conservation Service as having a significant limitation for building site development;

(ii) Those coastal areas mapped as class u (unstable), uos (unstable old slides), and urs (unstable recent slides) in the department of ecology Washington coastal atlas; or

(iii) Areas designated as quaternary slumps, earthflows, mudflows, lahars, or landslides on maps published by the United States Geological Survey or Washington department of natural resources.

(b) Areas with all three of the following characteristics:

(i) Slopes steeper than 15 percent;

(ii) Hillsides intersecting geologic contacts with a relatively permeable sediment overlying a relatively impermeable sediment or bedrock; and

(iii) Springs or groundwater seepage.

(c) Areas that have shown movement during the holocene epoch (from 10,000 years ago to the present) or which are underlain or covered by mass wastage debris of this epoch;

(d) Slopes that are parallel or subparallel to planes of weakness (such as bedding planes, joint systems, and fault planes) in subsurface materials;

(e) Slopes having gradients steeper than 80 percent subject to rockfall during seismic shaking;

(f) Areas potentially unstable as a result of rapid stream incision, stream bank erosion, and undercutting by wave action, including stream channel migration zones;

(g) Areas that show evidence of, or are at risk from snow avalanches;

(h) Areas located in a canyon or on an active alluvial fan, presently or potentially subject to inundation by debris flows or catastrophic flooding; and

(i) Any area with a slope of 40 percent or steeper and with a vertical relief of 10 or more feet except areas composed of bedrock. A slope is delineated by establishing its toe and top and measured by averaging the inclination over at least 10 feet of vertical relief.

(7) Seismic hazard areas must include areas subject to severe risk of damage as a result of earthquake induced ground shaking, slope failure, settlement or subsidence, soil liquefaction, surface faulting, or tsunamis. Settlement and soil liquefaction conditions occur in areas underlain by cohesionless soils of low density, typically in association with a shallow groundwater table. One indicator of potential for future earthquake damage is a record of earthquake damage in the past. Ground shaking is the primary cause of earthquake damage in Washington, and ground settlement may occur with shaking. The strength of ground shaking is primarily affected by:

(a) The magnitude of an earthquake;

(b) The distance from the source of an earthquake;

(c) The type or thickness of geologic materials at the surface; and

(d) The type of subsurface geologic structure.

(8) Other geological hazard areas:

(a) Volcanic hazard areas must include areas subject to pyroclastic flows, lava flows, debris avalanche, or inundation by debris flows, lahars, mudflows, or related flooding resulting from volcanic activity.

(b) Mine hazard areas are those areas underlain by, adjacent to, or affected by mine workings such as audits, gangways, tunnels, drifts, or air shafts. Factors which should be considered include: Proximity to development, depth from ground surface to the mine working, and geologic material.

6.2 Mapping of geologically hazardous areas (21.04.510)

The map referenced by name in the code (WWMC 21.04.510.A), *Critical Area Map 4: Geologically hazardous areas*, was not readily found. Recommend revising the language to more generally reference publicly available geologically hazardous areas maps. Retain provision B (WWMC 21.04.510.B), stating that public geologic hazard area maps are advisory, as-is.

7. FISH AND WILDLIFE HABITAT CONSERVATION AREAS (WWMC 21.04.600 - 671)

Table 6. Fish and Wildlife Habitat Conservation Areas review summary.

21.04.600	Fish and wildlife habitat conservation areas – Designation	Consider adding reference to the 2023 WDFW PHS List.	
21.04.600	Fish and wildlife habitat conservation areas – Designation	Add reference to the 2023 WDFW PHS List	BAS
21.04.610	Fish and wildlife habitat conservation areas – Mapping	Update the map reference	Clarity
21.04.620	Fish and wildlife habitat conservation areas – Water bodies – Allowed uses	No comments or suggestions	
21.04.630	Critical area report – Additional requirements for habitat conservation areas	Increase FWHCA documentation in vicinity of subject property.	BAS
21.04.640	Performance standards – General requirements	No comments or suggestions	

21.04.600	Fish and wildlife habitat conservation areas – Designation	Consider adding reference to the 2023 WDFW PHS List.	
21.04.650	Performance standards – Specific habitats	1. Recommend adding shrubsteppe to the priority habitats listed. 2. Review stream protections against current WDFW recommendations. 3. Clean up table to remove extraneous information and undefined terms.	1. BAS 2. BAS 3. Clarity
21.04.660	Performance standards – Subdivisions	Consider adding habitat corridor review requirements	BAS
21.04.670	Fish and wildlife habitat conservation areas – Piped streams	Consider adding incentives to daylight stream segments	BAS
21.04.671	Fish and wildlife habitat conservation areas – Mitigation standards	No comments or suggestions	
21.04.700	Landfill vicinity development standards	No comments or suggestions	

7.1 Fish and Wildlife Habitat Conservation Areas – Designation (21.04.600)

The Fish and Wildlife Habitat Conservation Areas (FWHCA) designation criteria can be improved by referencing WDFW Priority Habitat and Species (PHS) list current or as amended. This approach ensures CAO designations remain current with evolving state wildlife data without requiring formal ordinance amendment each time the PHS list is updated.

7.2 Fish and Wildlife Habitat Conservation Areas – Mapping (21.04.610)

The map referenced by name in the code (WWMC 21.04.610.A), *Critical Area Map 5: Fish and Wildlife Habitat Conservation Areas'*, was not readily found. Recommend revising the language to more generally reference publicly available FWHCA maps. Retain provision B (WWMC 21.04.610.B), stating that public FWHCA maps are advisory, as-is.

7.3 Critical area report – Additional requirements for habitat conservation areas (21.04.630)

21.04.630.B.2 limits documentation of priority habitats and species to within 200 feet of the project area. However, some species are impacted at a distance of more than 200 feet. We recommend increasing this screening area to be more protective and allow full consideration of WDFW management recommendations. The City may establish appropriate screening area on a site-specific basis considering conditions that constitute a significant disturbance, like urban land use.

7.4 Performance standards—Specific habitats. (21.04.650)

Shrubsteppe Habitat

Recommend adding shrubsteppe habitat to this code section. Shrubsteppe is a priority habitat on the WDFW PHS List. WDFW PHS on the web maps several shrubsteppe habitat patches within the City. This habitat also supports other listed species, like Ferruginous hawk.

Riparian habitat areas – BAS summary

Review WDFW BAS synthesis (Rentz et al. 2020) and recommendations for riparian protections summarized in the *Draft Best Available Science Review, Critical Areas Ordinance Update, Walla Walla County,* Section 6.4 (Facet 2026). Current WDFW riparian protection recommendations are based on soil type and dominant site potential tree height (SPTH) after 200 years of growth. Under this SPTH approach, WDFW no longer recommends using a stream classification system based on fish use. All streams are recognized as performing important functions, and the $SPTH_{200}$ model seeks to achieve full ecological function.

However, the City of Walla Walla contains no forested ecosystems and is all mapped by WDFW as a dryland ecosystem. In dryland ecosystems, WDFW recommends first identifying the full extent of the riparian vegetative community. Then overlaying a minimum 100-foot riparian buffer. The wider of the two riparian protection areas would apply on a site-specific basis; this is referred to as the zone of influence. It is commonly applied in non-forested environments like shrubsteppe. Width may alternatively be based on desired pollutant removal efficacy. As stated in WDFW Riparian Ecosystems: Volume 1 (bold emphasis added)(Quinn, Wilhere and Krueger 2020):

> *In dryland ecoregions, the width of the riparian ecosystem is based on the ecological function that creates the widest zone of influence. At most sites, this will be either the wood (large and small) or pollutant removal functions.* ***For grass, herb, shrub, and small tree vegetation types, the zone of influence based on wood, which depends on vegetation height, will be narrower than the zone of influence based on pollutant removal.*** *Therefore,* ***if pollutants, including sediments due to ground disturbance, are a concern at a particular site, then riparian ecosystem width should be based on the desired removal efficacy for pollutants created at that site.*** *If, for instance, surface run-off containing excess nitrogen is a concern and a 95% removal is desired, then the zone of influence is 170 ft (52 m) wide, measured from the*

active channel, see Table 5.4. If pollutant removal is not a concern, then riparian ecosystem width should be based on site-potential vegetation height (i.e., trees or shrubs), which should provide maximum wood and shade for aquatic habitats.

Given this information, the riparian protection widths WDFW recommends for Walla Walla range from 100-feet to 170-feet as measured from the ordinary high water mark or channel migration zone, whichever is greater.

A 100-foot-wide buffer is estimated to achieve 95 percent pollution removal and approximately 85 percent surface nitrogen (Rentz, et al. 2020). RMZ buffer recommendations presume the area is densely vegetated with native plants. WDFW recognizes that this increases existing non-conformity and recommends addressing that through non-conforming use regulations. In summary, a minimum buffer width of 100 feet for all streams aligns with BAS if SPTH/dryland ecosystem widths are not used for RMZ determinations.

The City must review the BAS-based recommendations and determine the best regulatory approach for the City of Walla Walla. We recommend reviewing water-quality buffer functions alongside stormwater management regulations. In general, urban settings are limited by surrounding land uses; review of buffer widths should be paired with consideration of requirements to enhance ecological functions. Currently, regulatory buffers range from 35 to 100 feet, depending on stream type. Most streams in the City currently require a 35-foot buffer. The current approach does not meet the minimum recommendations of the WDFW guidance.

Other Stream Management Recommendations

The following WDFW riparian management recommendations for urban areas should also be considered for implementation (Rentz et al. 2020):

- maintaining and improving functions through regulatory and voluntary means,
- identifying and prioritizing restoration,
- maintaining and improving riparian connections, and
- applying stormwater management.

We recommend reviewing WDFW PHS guidelines to determine appropriate protection measures for streams in Walla Walla and to update buffer width requirements. A minimum 100-foot buffer is recommended for water quality. If the City wants to incorporate nonscientific information as the basis for departing from BAS-recommendations, then the city must comply with WAC 365-195-915 below (bold emphasis added).

WAC 365-195-915. Criteria for including the best available science in developing policies and development regulations.

(1) To demonstrate that the best available science has been included in the development of climate resiliency and critical areas policies and regulations, counties and cities should address each of the following on the record:

(a) The specific policies and development regulations adopted to protect the functions and values of the critical areas at issue.

(b) The relevant sources of best available scientific information included in the decision-making.

(c) ***Any nonscientific information—including legal, social, cultural, economic, and political information—used as a basis for climate resiliency and critical area policies and regulations that depart from recommendations derived from the best available science. A county or city departing from science-based recommendations should:***

(i) Identify the information in the record that supports its decision to depart from science-based recommendations;

(ii) Explain its rationale for departing from science-based recommendations; and

(iii) Identify potential risks to climate resiliency, the functions and values of the critical area or areas at issue, and any additional measures chosen to limit such risks. State Environmental Policy Act (SEPA) review often provides an opportunity to establish and publish the record of this assessment.

(2) Counties and cities should include the best available science in determining whether to grant applications for administrative variances and exemptions from generally applicable provisions in policies and development regulations adopted to protect the functions and values of critical areas. Counties and cities should adopt procedures and criteria to ensure that the best available science is included in every review of an application for an administrative variance or exemption.

7.4.1 Riparian habitat areas (21.04.650.D.2)

To align with BAS, recommend adding channel migration zone or ordinary high water mark, whichever is greater to width measurements provision (b).

Recommend deleting repetitive language from (c). Overlapping critical area buffers are already addressed in (3) below. Also suggest adding language to (c) to clarify when and how buffers are modified to account for existing development that functionally interrupt buffers.

7.4.2 Buffer widths (21.04.650, Table 6)

Recommend applying 100-foot buffer to all streams to align with WDFW dryland ecosystem model as described in the riparian habitat areas – BAS summary above.

Remove waterway category column since it is not used anywhere else in the code and is not defined.

Remove existing conditions/targeted functions from table. This information is not used to determine buffer widths and information may be out-of-date. For example, the methodology for measuring the 'existing riparian average' is not clear and all those widths are less than required buffers. The CREP minimum can be retained as a footnote or moved to a separate code provision. Lastly, stormwater management is regulated under Title 13 – Water and Sewers. Stormwater management can also be noted in the stream buffer regulations under measures recommended for protection.

7.4.3 Buffer modification options (21.04.650.D.4 – 6)

Review buffer modification options in detail once updates to stream/riparian buffers are established. Buffer decreases below the 100-foot minimum recommended for water quality would need to demonstrate water quality is maintained. If buffer averaging is retained, water quality protection should be demonstrated. The City's stormwater design standards can be added to the buffer averaging criteria.

Standard riparian/buffer width recommendation presume a native plant community is present. Therefore, buffer reduction with enhancement is not supported by BAS. Recommend deleting 21.04.650.D.6.

7.5 Performance standards—Subdivisions (21.04.660)

Subdivisions of land may impact wildlife movement and corridors. To aid consideration of habitat corridor impacts during project permitting, the City may add language to protect wildlife corridors, supported by BAS and qualified professional reports.

7.6 Fish and wildlife habitat conservation areas – Piped streams (21.04.670)

Walla Walla may consider adding provisions which provide incentives for daylighting streams as a strategy to promote instream habitat restoration. This would support WDFW's recommendations to identify and prioritize restoration and improve riparian connections.

APPENDIX A. Guidance on Widths of Buffers (2018 and 2022)

Appendix 8-C

Guidance on Widths of Buffers and Ratios for Compensatory Mitigation for Use with the Western Washington Wetland Rating System

8C.1 Introduction

This appendix provides guidance on widths of buffers, ratios for compensatory mitigation, and other measures for protecting wetlands that are linked to the *Washington State Wetland Rating System for Western Washington: 2014 Update,* Department of Ecology Publication #14-06-029 (October 2014). Refer to Appendix 8-D for guidance for eastern Washington. Appendices 8-C through 8-F have been formatted similar to the main text of this volume (i.e., with a numbering system) to help with organization.

The tables below list the recommended widths of buffers for various alternatives, examples of measures to minimize impacts, and ratios for compensatory mitigation.

- **Table 8C-1.** Width of buffers needed to protect wetlands in western Washington if impacts from land use and wetland functions are NOT incorporated (Buffer Alternative 1). [Page 4]
- **Table 8C-2.** Width of buffers based on wetland category and modified by the intensity of the impacts from changes in proposed land use (Buffer Alternative 2). [Page 5]
- **Table 8C-3.** Types of land uses that can result in high, moderate, and low levels of impacts to adjacent wetlands (used in Buffer Alternatives 2 and 3). [Page 5]
- **Table 8C-4.** Width of buffers needed to protect Category IV wetlands in western Washington (Buffer Alternative 3). [Page 6]
- **Table 8C-5.** Width of buffers needed to protect Category III wetlands in western Washington (Buffer Alternative 3). [Page 6]
- **Table 8C-6**. Width of buffers needed to protect Category II wetlands in western Washington (Buffer Alternative 3). [Page 7]
- **Table 8C-7.** Width of buffers needed to protect Category I wetlands in western Washington (Buffer Alternative 3). [Page 8]
- **Table 8C-8.** Examples of measures to minimize impacts to wetlands from different types of activities. [Page 10]

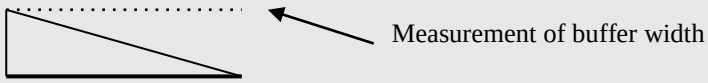
- **Table 8C-9.** Comparison of recommended buffer widths for high intensity land uses between Alternative 3 (step-wise scale) and Alternative 3A (graduated scale) based on score for habitat functions [Page 14].
- **Table 8C-10.** Comparison of recommended widths for buffers between Alternative 3 and Alternative 3A for proposed land uses with high impacts with mitigation for impacts. [Page 14]
- **Table 8C-11.** Mitigation ratios for projects in western Washington. [Page 20]

The guidance in this appendix can be used in developing regulations such as critical areas ordinances for protecting and managing the functions and values of wetlands. The recommendations are based on the analysis of the current scientific literature found in Volume 1. The detailed rationale for the recommendations is provided in Appendices 8-E and 8-F.

The recommendations on buffer widths and mitigation ratios are general, and there may be some wetlands for which these recommendations are either too restrictive or not protective enough. The recommendations are based on the assumption that a wetland will be protected only at the scale of the site itself. They do not reflect buffers and ratios that might result from regulations that are developed based on a larger landscape-scale approach.

8C.2 Widths of Buffers

Requiring buffers of a specific width has been one of the primary methods by which local jurisdictions in Washington have protected the functions and values of wetlands. Generally, buffers are the uplands adjacent to an aquatic resource that can, through various physical, chemical, and biological processes, reduce impacts to wetlands from adjacent land uses. The physical characteristics of buffers (e.g., slope, soils, vegetation, and width) determine how well buffers reduce the adverse impacts of human development. These characteristics are discussed in detail in Chapter 5, Volume 1.



In addition to reducing the impacts of adjacent land uses, buffers also protect and maintain a wide variety of functions and values provided by wetlands. For example, buffers can provide the terrestrial habitats needed by many species of wildlife that use wetlands to meet some of their needs.

The review of the scientific literature has shown, however, that buffers alone cannot adequately protect all functions that a wetland performs. Additional guidance is, therefore, provided on other ways in which wetlands can be managed and regulated to provide some of the necessary protection that buffers alone do not provide. The following guidance for protecting the functions and values of wetlands is based on their category as determined through the rating system for western Washington.

Basic assumptions for using the guidance on widths for buffers

Recommendations for widths of buffers assume that:

- The wetland has been categorized using the *Washington State Wetland Rating System for Western Washington: 2014 Update*, Department of Ecology Publication #14-06-029, October 2014.
- The buffer is vegetated with native plant communities that are appropriate for the *ecoregion* or with a plant community that provides similar functions. Ecoregions denote areas of general similarity in ecosystems and in the type, quality, and quantity of environmental resources. The U.S. Environmental Protection Agency maintains updated maps of 7ecoregions that are available at http://www.epa.gov/naaujydh/pages/models/ecoregions.htm . Ecoregions currently mapped for Washington are: Coast Range, Puget Lowland, Cascades, Eastern Cascades Slopes and Foothills, North Cascades, Columbia Plateau, Blue Mountains, and Northern Rockies.
- If the vegetation in the buffer is disturbed (grazed, mowed, etc.), proponents planning changes to land use that will increase impacts to wetlands need to rehabilitate the buffer with native plant communities that are appropriate for the ecoregion, or with a plant community that provides similar functions.
- The width of the buffer is measured along the horizontal plane (see drawing below):

- The buffer will remain relatively undisturbed in the future within the width specified.

Three alternatives for protecting the functions of wetlands using buffers are described in the following sections:

- **Buffer Alternative 1.** Width based only on wetland category.
- **Buffer Alternative 2.** Width based on wetland category and the intensity of impacts from proposed changes in land use.
- **Buffer Alternative 3.** Width based on wetland category, intensity of impacts, and wetland functions or special characteristics. This alternative has two options for determining the widths of buffers when they are based on the score for habitat. Alternative 3 provides three buffer widths based on habitat scores, while Alternative 3A provides a graduated scale of widths for buffers based on habitat scores.

The buffer widths recommended for each alternative were based on the review of scientific information in Volume 1. The guidance in this appendix synthesizes the information about the types and sizes of buffers needed to protect the functions and special characteristics of wetlands.

Appendices 8-C and 8-D do not provide the metric equivalents for buffer widths even though most of the research on buffers uses the metric scale. This decision was made because most local governments use the English Customary measures. For example, a buffer width is set at 50 feet rather than 15 meters.

8C.2.1 Buffer Alternative 1: Width Based Only on Wetland Category

This alternative, in which the width of buffers is based only on the category of the wetland, is the simplest (Table 8C-1). The width recommended for each category of wetland in Alternative 1 is the widest recommended for that category in both Alternatives 2 and 3 (discussed below). Alternative 1 provides the least flexibility because many different types of wetlands and types of human impacts are combined. For example, not all wetlands that fall into Category I or II need a 300-foot buffer. If no distinctions are made between the wetlands that fall into Category I or II, all wetlands that fall into these categories have to be protected with a 300-foot buffer so adequate protection is provided for those wetlands that do need a buffer this wide. Also, the widths recommended for this alternative are those needed to protect the wetland from proposed land uses that have the greatest impacts since no distinctions between impacts are made.

Table 8C-1. Width of buffers needed to protect wetlands in western Washington if impacts from land use and wetland functions are NOT incorporated (Buffer Alternative 1).

Category of Wetland	Widths of Buffers
IV	50 ft
III	150 ft
II	300 ft
I	300 ft

8C.2.2 Buffer Alternative 2: Width Based on Wetland Category and Modified by the Intensity of the Impacts from Proposed Land Use

The second alternative increases the regulatory flexibility by including the concept that not all proposed changes in land uses have the same level of impact (Table 8C-2). For example, one new residence being built on 5 acres of land near a wetland is expected to have a smaller impact than 20 houses built on the same 5 acres. Three categories of impacts from proposed land uses are outlined: land uses that can create high impacts, moderate impacts, and low impacts to wetlands. Different land uses that can cause these levels of impacts are listed in Table 8C-3.

Table 8C-2. Width of buffers needed to protect wetlands in western Washington considering impacts of proposed land uses (Buffer Alternative 2)**.**

Category of Wetland	Land Use with Low Impact *	Land Use with Moderate Impact *	Land Use with High Impact*
IV	25 ft	40 ft	50 ft
III	75 ft	110 ft	150 ft
II	150 ft	225 ft	300 ft
I	150 ft	225 ft	300 ft
* See Table 8C-3 below for types of land uses that can result in low, moderate, and high impacts to wetlands.			

Table 8C-3. Types of proposed land use that can result in high, moderate, and low levels of impacts to adjacent wetlands.

Level of Impact from Proposed Change in Land Use	Types of Land Use Based on Common Zoning Designations *
High	• Commercial • Urban • Industrial • Institutional • Retail sales • Residential (more than 1 unit/acre) • Conversion to high-intensity agriculture (dairies, nurseries, greenhouses, growing and harvesting crops requiring annual tilling and raising and maintaining animals, etc.) • High-intensity recreation (golf courses, ball fields, etc.) • Hobby farms
Moderate	• Residential (1 unit/acre or less) • Moderate-intensity open space (parks with biking, jogging, etc.) • Conversion to moderate-intensity agriculture (orchards, hay fields, etc.) • Paved trails • Building of logging roads • Utility corridor or right-of-way shared by several utilities and including access/maintenance road
Low	• Forestry (cutting of trees only) • Low-intensity open space (hiking, bird-watching, preservation of natural resources, etc.) • Unpaved trails • Utility corridor without a maintenance road and little or no vegetation management.
* Local governments are encouraged to create land-use designations for zoning that are consistent with these examples.	

8C.2.3 Buffer Alternative 3: Width Based on Wetland Category, Intensity of Impacts, Wetland Functions, or Special Characteristics

The third alternative provides the most flexibility by basing the widths of buffers on three factors: the wetland category, the intensity of the impacts (as used in Alternative 2), and the functions or special characteristics of the wetland that need to be protected as determined through the rating system. The recommended widths for buffers are shown in Tables 8C-4 to 8C-7. Using this alternative, a wetland may fall into more than one category in the table. For example, an interdunal wetland may be rated a Category III wetland because it is an isolated interdunal wetland, but it may be rated a Category II wetland based on its score for functions.

If a wetland meets more than one of the characteristics listed in Tables 8C-4 to 8C-7, the buffer recommended to protect the wetland is the widest one. For example, if a Category I wetland (Table 8C-7) scores 8 points for habitat and 7 points for water quality functions, a 300-foot buffer is needed for land uses with high impacts because the widths needed to protect habitat are wider than those needed for the other functions.

Table 8C-4. Width of buffers needed to protect Category IV wetlands in western Washington (Buffer Alternative 3 for wetlands scoring less than 16 points for all functions).

Wetland Characteristics	Buffer Widths by Impact of Proposed Land Use	Other Measures Recommended for Protection
Score for all 3 basic functions is less than 16 points	Low - 25 ft Moderate – 40 ft High – 50 ft	No recommendations at this time[1]

[1] No information on other measures for protection was available at the time this document was written. The Washington State Department of Ecology will continue to collect new information for future updates to this document.

Table 8C-5. Width of buffers needed to protect Category III wetlands in western Washington (Buffer Alternative 3 for wetlands scoring 16 - 19 points for all functions).

Wetland Characteristics	Buffer Widths by Impact of Proposed Land Use	Other Measures Recommended for Protection
Moderate level of function for habitat (score for habitat 6 - 7 points)* *If wetland scores 8-9 habitat points, use Table 8C-6 for Category II buffers	Low - 75 ft Moderate – 110 ft High – 150 ft	No recommendations at this time
Score for habitat 3-5 points	Low - 40 ft Moderate – 60 ft High – 80 ft	No recommendations at this time

[1]

Table 8C-6. Width of buffers needed to protect Category II wetlands in western Washington (Buffer Alternative 3 for wetlands scoring 20 - 22 points for all functions or having the "Special Characteristics" identified in the rating system).

Wetland Characteristics	**Buffer Widths by Impact of Proposed Land Use** (Apply most protective if more than one criterion is met.)	**Other Measures Recommended for Protection**
High level of function for habitat (score for habitat 8 - 9 points)	Low - 150 ft Moderate – 225 ft High – 300 ft	Maintain connections to other habitat areas
Moderate level of function for habitat (score for habitat 6 - 7 points)	Low - 75 ft Moderate – 110 ft High – 150 ft	No recommendations at this time[2]
High level of function for water quality improvement and low for habitat (score for water quality 8 - 9 points; habitat less than 6 points)	Low - 50 ft Moderate – 75 ft High – 100 ft	No additional surface discharges of untreated runoff
Estuarine	Low - 75 ft Moderate – 110 ft High – 150 ft	No recommendations at this time[2]
Interdunal	Low - 75 ft Moderate – 110 ft High – 150 ft	No recommendations at this time[2]
Not meeting above characteristics	Low - 50 ft Moderate – 75 ft High – 100 ft	No recommendations at this time[2]

[2] See footnote on the previous page.

Table 8C-7. Width of buffers needed to protect Category I wetlands in western Washington (Buffer Alternative 3 for wetlands scoring 23 points or more for all functions or having the "Special Characteristics" identified in the rating system).

Wetland Characteristics	**Buffer Widths by Impact of Proposed Land Use** (Apply most protective if more than one criterion is met)	**Other Measures Recommended for Protection**
Wetlands Of High Conservation Value	Low - 125 ft Moderate – 190 ft High – 250 ft	No additional surface discharges to wetland or its tributaries No septic systems within 300 ft of wetland Restore degraded parts of buffer
Bogs	Low - 125 ft Moderate – 190 ft High – 250 ft	No additional surface discharges to wetland or its tributaries Restore degraded parts of buffer
Forested	Buffer width to be based on score for habitat functions or water quality functions	If forested wetland scores high for habitat, need to maintain connections to other habitat areas Restore degraded parts of buffer
Estuarine	Low - 100 ft Moderate – 150 ft High – 200 ft	No recommendations at this time[3]
Wetlands in Coastal Lagoons	Low - 100 ft Moderate – 150 ft High – 200 ft	No recommendations at this time[3]
High level of function for habitat (score for habitat 8 - 9 points)	Low – 150 ft Moderate – 225 ft High – 300 ft	Maintain connections to other habitat areas Restore degraded parts of buffer
Interdunal wetland with high level of function for habitat (score for habitat 8 - 9 points).	Low – 150 ft Moderate – 225 ft High – 300 ft	Maintain connections to other habitat areas Restore degraded parts of buffer
Moderate level of function for habitat (score for habitat 6 - 7 points)	Low – 75 ft Moderate – 110 ft High – 150 ft	No recommendations at this time[3]
High level of function for water quality improvement (8 – 9 points) and low for habitat (less than 6 points)	Low – 50 ft Moderate – 75 ft High – 100 ft	No additional surface discharges of untreated runoff
Not meeting any of the above characteristics	Low – 50 ft Moderate – 75 ft High – 100 ft	No recommendations at this time[3]

[3] See footnote on page 6.

8C.2.4 Special Conditions for a Possible Reduction in Buffer Widths

8C.2.4.1 Condition 1: Reduction in Buffer Width Based on Reducing the Intensity of Impacts from Proposed Land Uses

The buffer widths recommended for proposed land uses with high-intensity impacts to wetlands can be reduced to those recommended for moderate-intensity impacts under the following conditions:

- For wetlands that score moderate or high for habitat (6 points or more for the habitat functions), the width of the buffer can be reduced if both of the following criteria are met:

    1) A relatively undisturbed, vegetated corridor at least 100-feet wide is protected between the wetland and any other Priority Habitats as defined by the Washington State Department of Fish and Wildlife. The latest definitions of priority habitats and their locations are available on the WDFW web site at: http://wdfw.wa.gov/hab/phshabs.htm)

        The corridor must be protected for the entire distance between the wetland and the Priority Habitat by some type of legal protection such as a conservation easement.

    2) Measures to minimize the impacts of different land uses on wetlands, such as the examples summarized in Table 8C-8, are applied.

- For wetlands that score less than 6 points for habitat, the buffer width can be reduced to that required for moderate land-use impacts by applying measures to minimize the impacts of the proposed land uses (see examples in Table 8C-8).

Table 8C-8. Examples of measures to minimize impacts to wetlands from proposed change in land use that have high impacts. (This is not a complete list of measures.)

Examples of Disturbance	Activities and Uses that Cause Disturbances	Examples of Measures to Minimize Impacts
Lights	• Parking lots • Warehouses • Manufacturing • Residential	• Direct lights away from wetland
Noise	• Manufacturing • Residential	• Locate activity that generates noise away from wetland
Toxic runoff*	• Parking lots • Roads • Manufacturing • Residential areas • Application of agricultural pesticides • Landscaping	• Route all new, untreated runoff away from wetland while ensuring wetland is not dewatered • Establish covenants limiting use of pesticides within 150 ft of wetland • Apply integrated pest management
Stormwater runoff	• Parking lots • Roads • Manufacturing • Residential areas • Commercial • Landscaping	• Retrofit stormwater detention and treatment for roads and existing adjacent development • Prevent channelized flow from lawns that directly enters the buffer
Change in water regime	• Impermeable surfaces • Lawns • Tilling	• Infiltrate or treat, detain, and disperse into buffer new runoff from impervious surfaces and new lawns
Pets and human disturbance	• Residential areas	• Use privacy fencing; plant dense vegetation to delineate buffer edge and to discourage disturbance using vegetation appropriate for the ecoregion; place wetland and its buffer in a separate tract
Dust	• Tilled fields	• Use best management practices to control dust
* These examples are not necessarily adequate for minimizing toxic runoff if threatened or endangered species are present at the site.		

8C.2.4.2 Condition 2: Reductions in Buffer Widths Where Existing Roads or Structures Lie Within the Buffer

Where a legally established, non-conforming use of the buffer exists (e.g., a road or structure that lies within the width of buffer recommended for that wetland), proposed actions in the buffer may be permitted as long as they do not increase the degree of non-conformity. This means no increase in the impacts to the wetland from activities in the buffer.

For example, if a land use with high impacts (e.g., building an urban road) is being proposed next to a Category II wetland with a moderate level of function for habitat, a 150-foot buffer would be needed to protect functions (see Table 8C-6). If, however, an existing urban road is already present and only 50 feet from the edge of the Category II wetland, the additional 100 feet of buffer may not be needed if the road is being widened. A vegetated buffer on the other side of the road would not help buffer the existing impacts to the wetland from the road. If the existing road is resurfaced or widened (e.g., to add a sidewalk) along the upland edge, without any further roadside development that would increase the degree of non-conformity, the additional buffer is not necessary. The associated increase in impervious surface from widening a road, however, may necessitate mitigation for impacts from stormwater.

If, however, the proposal is to build a new development (e.g., shopping center) along the upland side of the road, the impacts to the wetland and its functions may increase. This would increase the degree of non-conformity. The project proponent would need to provide the additional 100 feet of buffer extending beyond the road or apply buffer averaging (see Section 8C.2.6).

8C.2.4.3 Condition 3: Reduction in Buffer Widths Through an Individual Rural Stewardship Plan

A Rural Stewardship Plan (RSP) is the product of a collaborative effort between rural property owners and a local government to tailor a management plan specific for a rural parcel of land. The goal of the RSP is better management of wetlands than what would be achieved through strict adherence to regulations. In exchange, the landowner gains flexibility in the widths of buffers required, in clearing limits, and in other requirements found in the regulations. For example, dense development in rural residential areas can be treated as having a low level of impact when the development of the site is managed through a locally approved RSP. The voluntary agreement includes provisions for restoration, maintenance, and long-term monitoring and specifies the widths of buffers needed to protect each wetland within the RSP.

8C.2.5 Conditions for Increasing the Width of, or Enhancing, the Buffer

8C.2.5.1 Condition 1: Buffer is Not Vegetated with Plants Appropriate for the Region

The recommended widths for buffers are based on the assumption that the buffer is vegetated with a native plant community appropriate for the ecoregion or with one that performs similar functions. If the existing buffer is unvegetated, sparsely vegetated, or vegetated with invasive species that do not perform needed functions, the buffer should either be planted to create the appropriate plant community or the buffer should be widened to ensure that adequate functions of the buffer are provided. Generally, improving the vegetation will be more effective than widening the buffer.

8C.2.5.2 Condition 2: Buffer Has a Steep Slope

The review of the literature (Volume 1) indicates that the effectiveness of buffers at removing pollutants before they enter a wetland decreases as the slope increases. If a buffer is to be based on the score for its ability to improve water quality (see Tables 8C-4 through 8C-7) rather than habitat or other criteria, then the buffer should be increased by 50% if the slope is greater than 30% (a 3-foot rise for every 10 feet of horizontal distance).

8C.2.5.3 Condition 3: Buffer Is Used by Species Sensitive to Disturbance

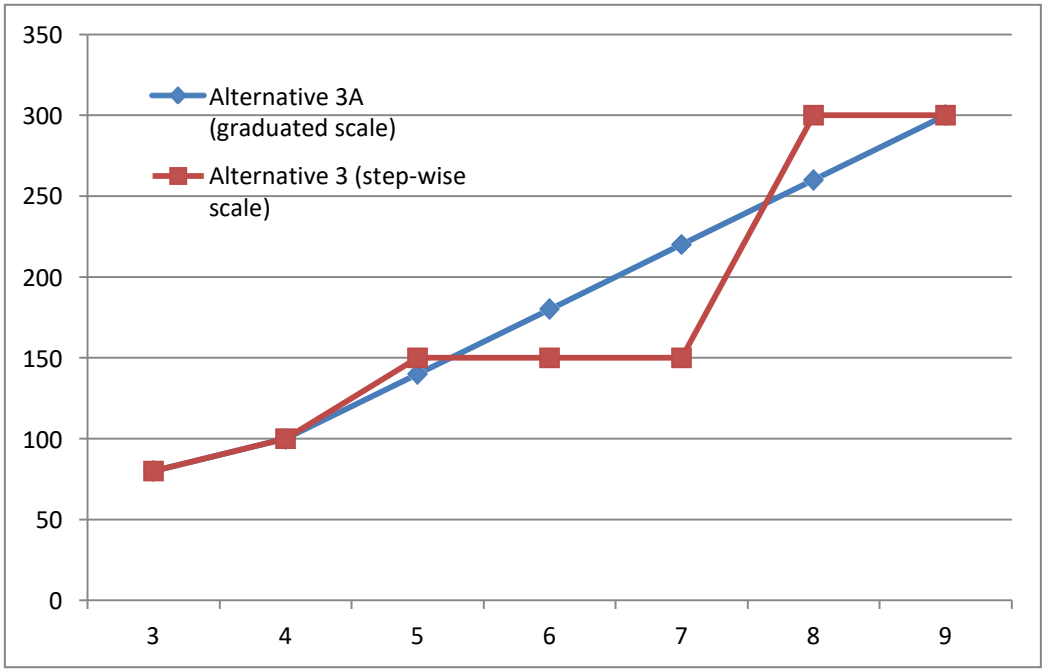
If the wetland provides habitat for a species that is particularly sensitive to disturbance (such as a threatened or endangered species), the width of the buffer should be increased to provide adequate protection for the species based on its particular, life-history needs. Some buffer requirements for priority species are available on the Washington State Department of Fish and Wildlife web page (http://wdfw.wa.gov/hab/phsrecs.htm). The list of priority species for vertebrates is at http://wdfw.wa.gov/hab/phsvert.htm; for invertebrates it is at http://wdfw.wa.gov/hab/phsinvrt.htm. Information on the buffer widths needed by some threatened, endangered, and sensitive species of wildlife is provided in Appendix 8-H.

8C.2.6 Buffer Averaging

The widths of buffers may be averaged if this will improve the protection of wetland functions, or if it is the only way to allow for reasonable use of a parcel. There is no scientific information available to determine if averaging the widths of buffers actually protects functions of wetlands. The authors have concluded that averaging could be allowed in the following situations:

Averaging may not be used in conjunction with any of the other provisions for reductions in buffers (listed above).

- Averaging to **improve wetland protection** may be permitted when **all** of the following conditions are met:
  - The wetland has significant differences in characteristics that affect its habitat functions, such as a wetland with a forested component adjacent to a degraded emergent component or a "dual-rated" wetland with a Category I area adjacent to a lower rated area
  - The buffer is increased adjacent to the higher-functioning area of habitat or more sensitive portion of the wetland and decreased adjacent to the lower-functioning or less sensitive portion
  - The total area of the buffer after averaging is equal to the area required without averaging
  - The buffer at its narrowest point is never less than 3/4 of the required width
- Averaging to **allow reasonable use** of a parcel may be permitted when **all** of the following are met:
  - There are no feasible alternatives to the site design that could be accomplished without buffer averaging
  - The averaged buffer will not result in degradation of the wetland's functions and values as demonstrated by a report from a qualified wetland professional (see Appendix 8-G for a definition of a qualified wetland professional)
  - The total buffer area after averaging is equal to the area required without averaging
  - The buffer at its narrowest point is never less than 3/4 of the required width



8C.2.7 Modifying Buffer Widths in Alternative 3 Using a Graduated Scale for the Habitat Functions (Alternative 3A)

Alternative 3 contains recommendations for protecting the habitat functions of wetlands using only three groupings of scores (3-4, 5-7, 8-9). As a result, a one-point difference between 4 and 5 and between 7 and 8 can result in a 50-foot increase in the width of a buffer around a wetland. The habitat scores were divided into three groups to simplify the regulations based on this guidance.

Such a large increase in width with a one-point increase in the habitat score may be contentious. A jurisdiction may wish to reduce the increments in the widths for buffers by developing a more graduated (but inherently more complicated) scale based on the scores for habitat. Table 8C-9 provides one example of a graduated scale for widths of buffers where the width increases for every one point increase in the habitat score.

Table 8C-9. Comparison of widths for buffers in Alternatives 3 (step-wise scale) and 3A (graduated scale) for proposed land uses with high impacts based on the score for habitat functions in western Washington

Points for Habitat from Wetland Rating Form	3	4	5	6	7	8	9
Alternative 3	80	100	150	150	150	300	300
Alternative 3A	80	100	140	180	220	260	300

Other scales are possible as long as they keep within the limits established from the scientific information currently available: wetlands with scores for habitat that are higher than 7 points need buffers that are at least 300 feet wide; wetlands with a score of 5-7 points need buffers of at least 150 feet; and wetlands with a score 3-4 points need buffers that are at least 80 feet wide.

These buffer widths can be further reduced by 25 percent if a proposed project with high impacts implements the mitigation measures such as those described in Table 8C-8. The measures are part of "Condition 1" in Section 8C.2.4 (Special Conditions for a Possible Reduction in Buffer Widths). The buffer widths under Buffer Alternatives 3 and 3A, and the corresponding 25 percent reduction (per buffer reduction condition 1) are shown in Table 8C-10.

Table 8C-10. Comparison of widths for buffers in Alternatives 3 (step-wise scale) and 3A (graduated scale) for proposed land uses with high impacts based on the score for habitat functions in western Washington if the impacts are mitigated.

Points for Habitat from Wetland Rating Form	3	4	5	6	7	8	9
Alternative 3 (with impact-reducing measures)	60	75	110	110	110	225	225
Alternative 3A (with impact-reducing measures	60	75	105	135	165	195	225

Alternatives 3 and 3A represent two separate approaches for determining widths of buffers for wetlands scoring between 5 and 8 points for the habitat functions. Local governments should select one of the two approaches and should not hybridize the approaches or adopt both at the same time.

Appendix D. Buffer Approaches for Eastern Washington

Option 1

Table 1. Wetland buffer width requirements, in feet, if Table 2 is implemented and a habitat corridor is provided

Category of wetland	Habitat Score 3-5 points (corridor not required)	Habitat Score 6-7 points	Habitat Score 8-9 points	Buffer width based on special characteristics
Category I & II: Based on rating of wetland functions (and not listed below)	75	110	150	NA
Category I & II: Forested	75	110	150	NA
Category I: Bogs, calcareous fens, and Wetlands of High Conservation Value	NA	NA	NA	190
Category I: Alkali	NA	NA	NA	150
Category II: Vernal pool	NA	NA	NA	150
Category III	60	110	150	NA
Category IV	40	40	40	NA

Impact minimization measures

Developments that produce the listed disturbances and are requesting a buffer reduction are required to address the disturbance through the use of applicable minimization measures.

This is not a complete list of measures, nor is every example measure required. Though not every measure is required, all effort should be made to implement as many measures as possible. Regulatory staff should determine, in coordination with the applicant, which measures are applicable and practicable.

Table 2. Impact minimization measures

Examples of disturbance	Activities and uses that cause disturbances	Examples of measures to minimize impacts
Lights	• Parking lots • Commercial/Industrial • Residential • Recreation (e.g., athletic fields) • Agricultural buildings	• Direct lights away from wetland • Only use lighting where necessary for public safety and keep lights off when not needed • Use motion-activated lights • Use full cut-off filters to cover light bulbs and direct light only where needed • Limit use of blue-white colored lights in favor of red-amber hues • Use lower-intensity LED lighting • Dim light to the lowest acceptable intensity
Noise	• Commercial • Industrial • Recreation (e.g., athletic fields, bleachers, etc.) • Residential • Agriculture	• Locate activity that generates noise away from wetland • Construct a fence to reduce noise impacts on adjacent wetland and buffer • Plant a strip of dense shrub vegetation adjacent to wetland buffer
Toxic runoff	• Parking lots • Roads • Commercial/industrial • Residential areas • Application of pesticides • Landscaping • Agriculture	• Route all new, untreated runoff away from wetland while ensuring wetland is not dewatered • Establish covenants limiting use of pesticides within 150 ft. of wetland • Apply integrated pest management (Note: These examples are not necessarily adequate for minimizing toxic runoff if threatened or endangered species are present at the site.)

Examples of disturbance	Activities and uses that cause disturbances	Examples of measures to minimize impacts
Stormwater runoff	• Parking lots • Roads • Residential areas • Commercial/industrial • Recreation • Landscaping/lawns • Other impermeable surfaces, compacted soil, etc.	• Retrofit stormwater detention and treatment for roads and existing adjacent development • Prevent channelized or sheet flow from lawns that directly enters the buffer • Infiltrate or treat, detain, and disperse new runoff from impervious surfaces and lawns
Pets and human disturbance	• Residential areas • Recreation	• Use privacy fencing • Plant dense native vegetation to delineate buffer edge and to discourage disturbance • Place wetland and its buffer in a separate tract • Place signs around the wetland buffer every 50-200 ft., and for subdivisions place signs at the back of each residential lot • When platting new subdivisions, locate greenbelts, stormwater facilities, or other lower-intensity land uses adjacent to wetland buffers
Dust	• Tilled fields • Roads	• Use best management practices to control dust

Table 3. Wetland buffer width requirements, in feet, for applicants not providing a habitat corridor or implementing measures in Table 2

Category of wetland	Habitat score 3-5 points	Habitat score 6-7 points	Habitat score 8-9 points	Buffer width based on special characteristics
Category I & II: Based on rating of wetland functions (and not listed below)	100	150	200	NA
Category I & II: Forested	100	150	200	NA
Category I: Bogs, calcareous fens, and Wetlands of High Conservation Value	NA	NA	NA	250
Category I: Alkali	NA	NA	NA	200
Category II: Vernal pool	NA	NA	NA	200
Category III	80	150	200	NA
Category IV	50	50	50	NA

Conditions for implementing Tables 1, 2, and 3

1. Wetlands that score 6 points or more for habitat function: the buffers in Table 1 can be used only if all of the following criteria are met:

a. A relatively undisturbed, vegetated corridor at least 100 feet wide is protected between the wetland and:

i. A legally protected, relatively undisturbed and vegetated area (e.g., Priority Habitats, compensatory mitigation sites, wildlife areas/refuges, national, county, and state parks where they have management plans with identified areas designated as Natural, Natural Forest, or Natural Area Preserve, or

ii. An area that is the site of a Watershed Project identified within, and fully consistent with, a Watershed Plan as defined by RCW 89-08-460, or

iii. An area where development is prohibited according to the provisions of the local shoreline master program, or

iV. An area with equivalent habitat quality that has conservation status in perpetuity, in consultation with WDFW.

b. The corridor is permanently protected for the entire distance between the wetland and the shoreline or legally protected area by a conservation easement, deed restriction, or other legal means.

c. Presence or absence of the shoreline or Priority Habitat must be confirmed by a qualified biologist or shoreline Administrator.

d. The measures in Table 2 are implemented, as applicable, to minimize the impacts of the adjacent land uses.

2. For wetlands that score 5 or fewer habitat points, only the measures in Table 2 are required for the use of the buffers in Table 1.

3. If an applicant does not apply the mitigation measures in Table 2 or is unable to provide a protected corridor, then the buffers in Table 3 shall be used.

4. The buffer widths in Tables 1 and 3 assume that the buffer is vegetated with a native plant community appropriate for the ecoregion. If the existing buffer is un-vegetated, sparsely vegetated, or vegetated with invasive species that do not perform needed functions, the buffer must either be planted to create the appropriate native plant community or be widened to ensure that the buffer provides adequate functions to protect the wetland.

Note: An expanded table with graduated buffer widths based on habitat score is also outlined in the July 2018 Appendix 8-D[77] of *Wetlands in Washington State, Volume 2*. This is an approach that assigns unique buffer widths to each habitat score in seven increments. It is a gradual increase in buffer width with each point. Compared to Option 1, this avoids a marked increase in buffer width resulting from an increase of one point in the habitat score.

Option 2

Table 1. Width of buffers, in feet, needed to protect wetlands from impacts of proposed land uses (used with Table 2)

Category of wetland	Land use with low impact*	Land use with moderate impact*	Land use with high impact*
I	125	190	250
II	100	150	200
III	75	110	150
IV	25	40	50

*See Table 2 below for types of land uses that can result in low, moderate, and high impacts to wetlands

Table 2. Levels of impacts from proposed land use types

[Local governments are encouraged to ensure the uses in this table match the uses specified in their development and land use regulations and are consistent with the principles in this example.]

Level of impact from proposed land use	Types of land use
High	• Commercial • Urban • Industrial • Institutional • Mixed-use developments • Residential (more than 1 unit/acre) • Roads: federal and state highways, including on-ramps and exits, state routes, and other roads associated with high-impact land uses • Railroads • Agriculture with high-intensity activities (dairies, nurseries, greenhouses, growing and harvesting crops requiring annual tilling, raising and maintaining animals, etc.)

[77] https://apps.ecology.wa.gov/publications/parts/0506008part4.pdf

Level of impact from proposed land use	Types of land use
	• Open/recreational space with high-intensity uses (golf courses, ball fields, etc.) • Solar farms (utility scale)
Moderate	• Residential (1 unit/acre or less) • Roads: Forest Service roads and roads associated with moderate-impact land uses • Open/recreational space with moderate-intensity uses (parks with paved trails or playgrounds, biking, jogging, etc.) • Agriculture with moderate-intensity uses (orchards, hay fields, light or rotational grazing, etc.) • Utility corridor or right-of-way used by one or more utilities and including access/maintenance • Wind farm
Low	• Natural resource lands (forestry/silviculture–cutting of trees only, not land clearing and removing stumps) • Open/recreational space with low-intensity uses (unpaved trails, hiking, birdwatching, etc.) • Utility corridor without a maintenance road and little or no vegetation management • Cell tower

Option 3

Table 1. Wetland buffer width requirements, in feet, based solely on wetland category

Category of wetland	Buffer width
I	250
II	200
III	150
IV	50

APPENDIX B. Ratios for Compensatory Mitigation for Use with the Eastern Washington Wetland Rating System (2018 and 2022)

8C.3 Ratios for Compensatory Mitigation

When the acreage required for compensatory mitigation is divided by the acreage of impact, the result is a number known variously as a *replacement*, *compensation*, or *mitigation* ratio. Compensatory mitigation ratios are used to help ensure that compensatory mitigation actions are adequate to offset unavoidable wetland impacts by requiring a greater amount of mitigation area than the area of impact. Requiring greater mitigation area helps compensate for the risk that a mitigation action will fail and for the time lag that occurs between the wetland impact and achieving a fully functioning mitigation site.

8C.3.1 Definitions of Types of Compensatory Mitigation

The ratios presented are based on the type of compensatory mitigation proposed (e.g., restoration, creation, and enhancement). In its *Regulatory Guidance Letter 02-02*, the U.S. Army Corps of Engineers provided definitions for these types of compensatory mitigation. For consistency, the authors of this document use the same definitions which are provided below.

Restoration: The manipulation of the physical, chemical, or biological characteristics of a site with the goal of returning natural or historic functions to a former or degraded wetland. For the purpose of tracking net gains in wetland acres, restoration is divided into:

- **Re-establishment.** The manipulation of the physical, chemical, or biological characteristics of a site with the goal of returning natural or historic functions to a **former** wetland. Re-establishment results in a gain in wetland acres (and functions). Activities could include removing fill material, plugging ditches, or breaking drain tiles.
- **Rehabilitation.** The manipulation of the physical, chemical, or biological characteristics of a site with the goal of repairing natural or historic functions of a **degraded** wetland. Rehabilitation results in a gain in wetland function but does not result in a gain in wetland acres. Activities could involve breaching a dike to reconnect wetlands to a floodplain or return tidal influence to a wetland.

Creation (Establishment): The manipulation of the physical, chemical, or biological characteristics present to develop a wetland on an upland or deepwater site where a wetland did not previously exist. Establishment results in a gain in wetland acres. Activities typically involve excavation of upland soils to elevations that will produce a wetland hydroperiod, create hydric soils, and support the growth of hydrophytic plant species.

Enhancement: The manipulation of the physical, chemical, or biological characteristics of a wetland site to heighten, intensify, or improve specific function(s) or to change the growth stage or composition of the vegetation present. Enhancement is undertaken for specified purposes such as water quality improvement, flood water retention, or wildlife

habitat. Enhancement results in a change in some wetland functions and can lead to a decline in other wetland functions, but does not result in a gain in wetland acres. Activities typically consist of planting vegetation, controlling non-native or invasive species, modifying site elevations or the proportion of open water to influence hydroperiods, or some combination of these activities.

Protection/Maintenance (Preservation): Removing a threat to, or preventing the decline of, wetland conditions by an action in or near a wetland. This includes the purchase of land or easements, repairing water control structures or fences, or structural protection such as repairing a barrier island. This term also includes activities commonly associated with the term *preservation*. Preservation does not result in a gain of wetland acres, may result in a gain in functions, and will be used only in exceptional circumstances.

Distinction between rehabilitation and enhancement

The distinction between rehabilitation and enhancement as defined above is not clear-cut and can be hard to understand. Actions that rehabilitate or enhance wetlands span a continuum of activities that cannot be defined by specific criteria.

Rehabilitation ⟷ *Enhancement*

In general, rehabilitation involves actions that are more sustainable and that reinstate environmental processes, both at the site and landscape scale (e.g., reinstating hydrologic processes in a diked floodplain by breaching the dikes). Rehabilitation actions often focus on restoring environmental processes that have been disturbed or altered by previous or ongoing, human activity. Ecology further defines *rehabilitation* as:

- Actions that restore the original hydrogeomorphic (HGM) class, or subclass, to a wetland whose current HGM class, or subclass, has been changed by human activities
- Actions that restore the water regime that was present and maintained the wetland before human activities changed it

Any other actions taken in existing wetlands would be considered *enhancement.* Enhancement typically involves actions that provide gains in only one or a few functions and can lead to a decline in other functions. Enhancement actions often focus on structural or superficial improvements to a site and generally do not address larger-scale environmental processes.

For example, a wetland that was once a forested, riverine wetland was changed to a depressional, emergent wetland by the construction of a dike and through grazing. Rehabilitating the wetland would involve breaching the dike so the wetland becomes a riverine wetland again, discontinuing the grazing, and reforesting the area. Discontinuing the grazing and reforesting the wetland without re-establishing the links to the riverine system would be considered enhancement.

Basic assumptions for using the guidance on ratios

- The ratios are for a compensatory mitigation project that is concurrent with impacts to wetlands. If impacts are to be mitigated by using an approved and established mitigation bank, the rules and ratios applicable to the bank should be used.
- The ratios are based on the assumption that the category (based on the rating system for western Washington) and hydrogeomorphic (HGM) class or subclass of the wetland proposed as compensation are the same as the category and HGM class or subclass of the affected wetland (e.g., impacts to a Category II riverine wetland are compensated by creating, restoring, or enhancing a Category II riverine wetland).
- Ratios for projects in which the category and HGM class or subclass of wetlands proposed as compensation is not the same as that of the wetland affected will be determined on a case-by-case basis using the recommended ratios as a starting point. The ratios could be higher in such cases.
- The ratio for using rehabilitation as compensation is 2 times that for using re-establishment or creation (R/C) (2 acres of rehabilitation are equivalent to 1 acre of R/C). The ratio for using enhancement as compensation is 4 times that for using R/C (4 acres of enhancement are equivalent to 1 acre of R/C).
- Re-establishment or creation can be used in combination with rehabilitation or enhancement. For example, 1 acre of impact to a Category III wetland would require 2 acres of R/C. If an applicant provides 1 acre of R/C (i.e., replacing the lost acreage at a 1:1 ratio), the remaining 1 acre of R/C necessary to compensate for the impact could be substituted with 2 acres of rehabilitation or 4 acres of enhancement.
- Generally the use of enhancement alone as compensation is discouraged. Using enhancement in combination with the replacement of wetland area at a minimum of 1:1 through re-establishment or creation is preferred.

These ratios were developed to provide a starting point for further discussions with each proponent of compensatory mitigation. They are based on the observations of the success and risk of compensatory mitigation, as reviewed in Volume 1, and do not represent the specific risk or opportunities of any individual project.

As noted above, the ratios for compensatory mitigation are based on the assumption that the category and hydrogeomorphic (HGM) class or subclass of the affected wetland and the mitigation wetland are the same. The ratios may be adjusted either up or down if the category or HGM class or subclass of the wetland proposed for compensation is different. For example, ratios may be lower if impacts to a Category IV wetland are to be mitigated by creating a Category II wetland. The same is true for impacts to wetlands that currently would be considered *atypical* (see definition below).

Also, compensatory mitigation should not result in the creation, restoration, or enhancement of an atypical wetland. An atypical wetland is defined as a wetland whose

design does not match the type of wetland that would be found in the geomorphic setting of the proposed site (i.e., the water source(s) and hydroperiod proposed for the mitigation site are not typical for the geomorphic setting). In addition, any designs that provide exaggerated morphology or require a berm or other engineered structures to hold back water would be considered atypical. For example, excavating a permanently inundated pond in an existing seasonally saturated or inundated wetland is one example of an enhancement project that could result in an atypical wetland. Another example would be excavating depressions in an existing wetland on a slope that required the construction of berms to impound water.

On a case-by-case basis, it is possible to use the scores from the Washington State wetland rating system to compare functions between the mitigation wetland and the impacted wetland. This information may also be used to adjust replacement ratios. Scores from the methods for assessing wetland functions (Hruby et al. 1999) provide another option to establish whether the functions lost will be replaced if both the affected wetland and the wetland used for compensation are of the same HGM class and subclass.

Mitigation ratios for projects in western Washington are shown in Table 8C-11. Refer to the text box on the basic assumptions on the previous page before reading the table. As mentioned previously, these ratios were developed to provide a starting point for further discussions with each proponent of compensatory mitigation. They only factor in the observations of mitigation success and risk at a programmatic level, and do not represent the specific risk or opportunity of any individual project.

Table 8C-11. Mitigation ratios for projects in western Washington.

Category and Type of Wetland Impacts	Re-establishment or Creation	Rehabilitation Only[4]	Re-establishment or Creation (R/C) and Rehabilitation (RH)[4]	Re-establishment or Creation (R/C) and Enhancement (E)[4]	Enhancement Only[4]
All Category IV	1.5:1	3:1	1:1 R/C and 1:1RH	1:1 R/C and 2:1 E	6:1
All Category III	2:1	4:1	1:1 R/C and 2:1 RH	1:1 R/C and 4:1 E	8:1
Category II Estuarine	Case-by-case	4:1 Rehabilitation of an estuarine	Case-by-case	Case-by-case	Case-by-case
Category II Interdunal	2:1 Compensation has to be interdunal wetland	4:1 Compensation has to be interdunal wetland	1:1 R/C and 2:1 RH Compensation has to be interdunal wetland	Not considered an option[5]	Not considered an option[5]
All other Category II	3:1	6:1	1:1 R/C and 4:1 RH	1:1 R/C and 8:1 E	12:1
Category I Forested	6:1	12:1	1:1 R/C and 10:1 RH	1:1 R/C and 20:1 E	24:1
Category I based on score for functions	4:1	8:1	1:1 R/C and 6:1 RH	1:1 R/C and 12:1 E	16:1
Category I Natural Heritage site	Not considered possible[6]	6:1 Rehabilitation of a Natural Heritage site	R/C Not considered possible[6]	R/C Not considered possible[6]	Case-by-case
Category I Coastal Lagoon	Not considered possible[6]	6:1 Rehabilitation of a coastal lagoon	R/C not considered possible[6]	R/C not considered possible[6]	Case-by-case
Category I Bog	Not considered possible[6]	6:1 Rehabilitation of a bog	R/C Not considered possible[6]	R/C Not considered possible[6]	Case-by-case
Category I Estuarine	Case-by-case	6:1 Rehabilitation of an estuarine	Case-by-case	Case-by-case	Case-by-case
NOTE: Preservation is discussed in the following section.					

[4] These ratios are based on the assumption that the rehabilitation or enhancement actions implemented represent the average degree of improvement possible for the site. Proposals to implement more effective rehabilitation or enhancement actions may result in a lower ratio, while less effective actions may result in a higher ratio. The distinction between rehabilitation and enhancement is not clear-cut. Instead, rehabilitation and enhancement actions span a continuum. Proposals that fall within the gray area between rehabilitation and enhancement will result in a ratio that lies between the ratios for rehabilitation and the ratios for enhancement.

[5] Due to the dynamic nature of interdunal systems, enhancement is not considered an ecologically appropriate action.

[6] Natural Heritage sites, coastal lagoons, and bogs are considered irreplaceable wetlands because they perform some special functions that cannot be replaced through compensatory mitigation. Impacts to such wetlands would therefore result in a net loss of some functions no matter what kind of compensation is proposed.

8C.3.2 Conditions for Increasing or Reducing Replacement Ratios

Increases in replacement ratios are appropriate under the following circumstances:

- Success of the proposed restoration or creation is uncertain
- A long time will elapse between impact and establishment of wetland functions at the mitigation site
- Proposed mitigation will result in a lower category wetland or reduced functions relative to the wetland being impacted
- The impact was unauthorized

Reductions in replacement ratios are appropriate under the following circumstances:

- Documentation by a qualified wetland specialist (see Appendix 8-H) demonstrates that the proposed mitigation actions have a very high likelihood of success based on prior experience
- Documentation by a qualified wetland specialist demonstrates that the proposed actions for compensation will provide functions and values that are significantly greater than the wetland being affected
- The proposed actions for compensation are conducted in advance of the impact and are shown to be successful
- In wetlands where several HGM classes are found within one delineated boundary, the areas of the wetlands within each HGM class can be scored and rated separately and the ratios adjusted accordingly, if **all of the following** apply:
  - The wetland does not meet any of the criteria for wetlands with "Special Characteristics" as defined in the rating system
  - The rating and score for the entire wetland is provided along with the scores and ratings for each area with a different HGM class.
  - Impacts to the wetland are all within an area that has a different HGM class from the one used to establish the initial category
  - The proponents provide adequate hydrologic and geomorphic data to establish that the boundary between HGM classes lies at least 50 feet outside of the footprint of the impacts

8C.3.3 Replacement Ratios for Preservation

In some cases, preservation of existing wetlands may be acceptable as compensation for wetland losses. Acceptable sites for preservation include those that:

- Are important due to their landscape position
- Are rare or limited wetland types
- Provide high levels of functions

Ratios for preservation in combination with other forms of mitigation generally range from 10:1 to 20:1, as determined on a case-by-case basis, depending on the quality of the wetlands being impacted and the quality of the wetlands being preserved. Ratios for preservation as the sole means of mitigation generally start at 20:1. Specific ratios will depend upon the significance of the preservation project and the quality of the wetland resources lost.

See Chapter 8 (Section 8.3.7.2) and Appendix 8-B for more information on preservation and the criteria for its use as compensation.

8C.3.4 Replacement Ratios for Temporal Impacts and Conversions

When impacts to wetlands are not permanent, local governments often require some compensation for the temporal loss of wetland functions. *Temporal impacts* refer to impacts to those functions that will eventually be replaced but cannot achieve similar functionality in a short time. For example, clearing forested wetland vegetation for pipeline construction could result in the temporal loss of functions, such as song bird habitat provided by the tree canopy. It may take over 20 years to re-establish the level of function lost as a result of clearing the trees. Although the wetlands will be re-vegetated and over time it is anticipated that their previous level of functioning will be re-established, a temporal loss of functions will occur. There is also some risk of failure associated with the impacts or alterations, especially when soil is compacted by equipment, deep excavation is required, and pipeline trenches alter the water regime at the site.

Therefore, in addition to restoring the affected wetland to its previous condition, local governments should consider requiring compensation to account for the risk and temporal loss of wetland functions. Generally, the ratios for temporal impacts to forested and scrub-shrub wetlands are one-quarter of the recommended ratios for permanent impacts (refer to Table 8C-11), provided that the following measures are satisfied:

- An explanation of how hydric soil, especially deep organic soil, is stored and handled in the areas where the soil profile will be severely disturbed for a fairly significant depth or time

- Surface and groundwater flow patterns are maintained or can be restored immediately following construction
- A 10-year monitoring and maintenance plan is developed and implemented for the restored forest and scrub-shrub wetlands
- Disturbed buffers are re-vegetated and monitored
- Where appropriate, the hydroseed mix to be applied on re-establishment areas is identified

When impacts are to a native emergent community and there is a potential risk that its re-establishment will be unsuccessful, compensation for temporal loss and the potential risk should be required in addition to restoring the affected wetland and monitoring the site. If the impacts are to wetlands dominated by non-native vegetation (e.g., blackberry, reed canarygrass, or pasture grasses), restoration of the affected wetland with native species and monitoring after construction is generally all that is required.

Loss of functions due to the permanent conversion of wetlands from one type to another also requires compensation. When wetlands are not completely lost but are converted to another type, such as a forested wetland converted to an emergent or shrub wetland (e.g., for a utility right-of-way), some functions are lost or reduced.

The ratios for conversion of wetlands from one type to another will vary based on the degree of the alteration, but they are generally one-half of the recommended ratios for permanent impacts (refer to Table 8C-11).

Refer to Appendix 8-F for the rationale for the ratios provided in this appendix.

Specific guidance has been developed for conversions of wetlands to cranberry bogs. Please refer to the 1998 *Guidelines for Implementation of Compensatory Mitigation Requirements for Conversion of Wetlands to Cranberry Bogs* for information on ratios associated with this activity (Washington State Department of Ecology, U.S. Environmental Protection Agency Region 10, U.S. Army Corps of Engineers Seattle District, and U.S. Fish and Wildlife Service. 1998. Special Public Notice: http://www.nws.usace.army.mil/publicmenu/DOCUMENTS/ACF101C.pdf).

Appendix E. Mitigation Ratio Tables

Compensation ratios for permanent impacts (western and eastern Washington)

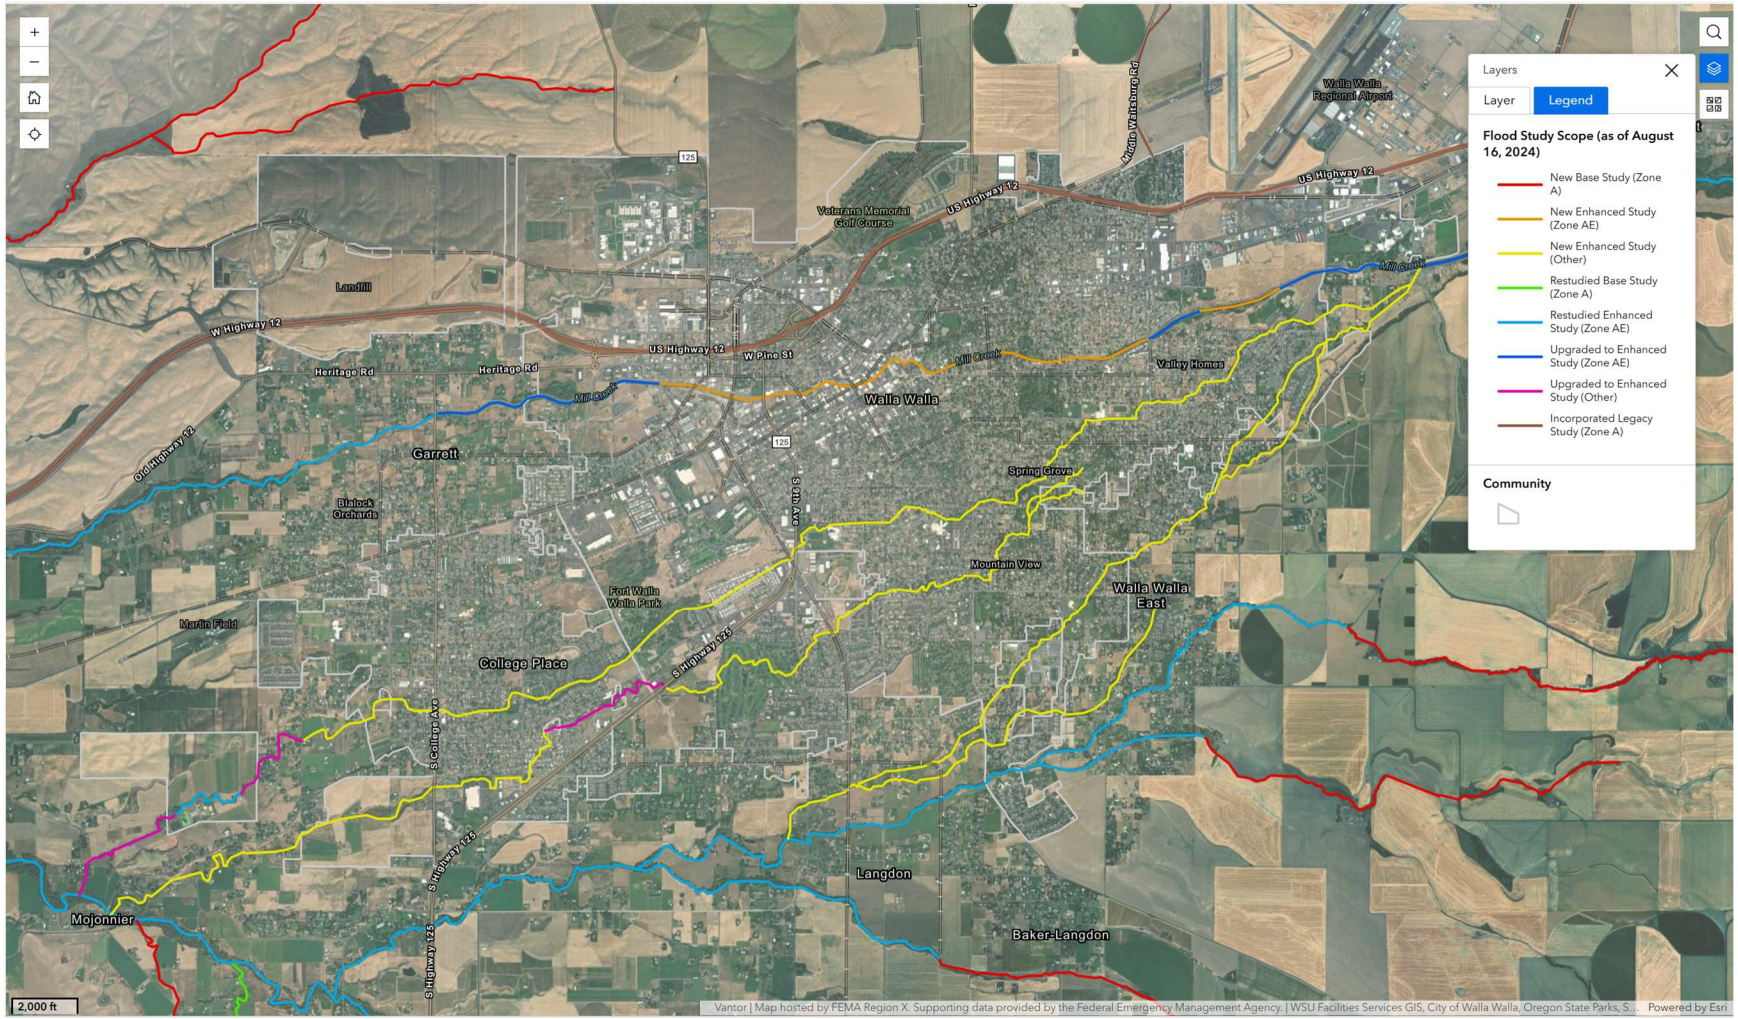


Table 1

Category of impacted wetland (based on score for function)	Re-establishment or creation	Rehabilitation	Preservation	Enhancement
Category I	4:1	8:1	16:1	16:1
Category II	3:1	6:1	12:1	12:1
Category III	2:1	4:1	8:1	8:1
Category IV	1.5:1	3:1	6:1	6:1

Notes:

- Ratios for rehabilitation, preservation, and enhancement may be reduced when combined with 1:1 replacement through re-establishment or creation. See Table 6B-2 in *Wetland Mitigation in Washington State – Part 1: Agency Policies and Guidance –Version 2* (Ecology et al., 2021 or as revised).
- All proposed preservation sites need to meet the preservation criteria listed in Chapter 070.3.E of Appendix A, Sample Wetland Regulations.
- The ratios provide in Table 1 are for permanent, direct impacts to wetlands. For recommended ratios for other types of impacts (e.g., long-term temporary, conversions), see Chapters 6B4.4 through 6B4.8 of *Wetland Mitigation in Washington State – Part 1: Agency Policies and Guidance –Version 2* (Ecology et al., 2021 or as revised).
- The category of impacted wetland is based on scores for functions. Compensation ratios in this table generally do not apply when impacts involve a wetland whose category is based on special characteristics. Compensation ratios for impacts to wetlands with special characteristics are provided in Table 2 below. Specific tables are provided for western and eastern Washington.

APPENDIX C. FEMA Flood Study Update Maps (2026)

FEMA Risk Map [Scope (Flood) | Walla Walla County, Washington - Risk MAP Portfolio]

Federal Emergency Management Agency

Washington, D.C. 20472

JUL 21 2006

CERTIFIED MAIL
RETURN RECEIPT REQUESTED

The Honorable David G. Carey
Chairman, Walla Walla County
Board of Commissioners
P.O. Box 1506
Walla Walla, WA 99362

IN REPLY REFER TO:
Case No.: 05-10-0491P
Community Name: Walla Walla County, WA
Community No.: 530194
Effective Date of This Revision: NOV 23 2006

Dear Mr. Carey:

The Flood Insurance Study report and Flood Insurance Rate Map for your community have been revised by this Letter of Map Revision (LOMR). Please use the enclosed annotated map panel(s) revised by this LOMR for floodplain management purposes and for all flood insurance policies and renewals issued in your community.

Additional documents are enclosed which provide information regarding this LOMR. Please see the List of Enclosures below to determine which documents are included. Other attachments specific to this request may be included as referenced in the Determination Document. If you have any questions regarding floodplain management regulations for your community or the National Flood Insurance Program (NFIP) in general, please contact the Consultation Coordination Officer for your community. If you have any technical questions regarding this LOMR, please contact the Director, Federal Insurance and Mitigation Division of the Department of Homeland Security's Federal Emergency Management Agency (FEMA) in Bothell, Washington, at (425) 487-4682, or the FEMA Map Assistance Center toll free at 1-877-336-2627 (1-877-FEMA MAP). Additional information about the NFIP is available on our website at http://www.fema.gov/nfip.

Sincerely,

Kevin C Long

Kevin C. Long, CFM, Project Engineer
Engineering Management Section
Mitigation Division

DETERMINATION

This document provides the determination from the Department of Homeland Security's Federal Emergency Management Agency (FEMA) regarding a request for a Letter of Map Revision (LOMR) for the area described above. Using the information submitted, we have determined that a revision to the flood hazards depicted in the Flood Insurance Study (FIS) report and/or National Flood Insurance Program (NFIP) map is warranted. This document revises the effective NFIP map, as indicated in the attached documentation. Please use the enclosed annotated map panels revised by this LOMR for floodplain management purposes and for all flood insurance policies and renewals in your community.

This determination is based on the flood data presently available. The enclosed documents provide additional information regarding this determination. If you have any questions about this document, please contact the FEMA Map Assistance Center toll free at 1-877-336-2627 (1-877-FEMA MAP) or by letter addressed to the LOMR Depot, 3601 Eisenhower Avenue, Alexandria, VA 22304. Additional Information about the NFIP is available on our website at http://www.fema.gov/nfip.

LETTER OF MAP REVISION
DETERMINATION DOCUMENT (CONTINUED)

COMMUNITY INFORMATION

APPLICABLE NFIP REGULATIONS/COMMUNITY OBLIGATION

We have made this determination pursuant to Section 206 of the Flood Disaster Protection Act of 1973 (P.L. 93-234) and in accordance with the National Flood Insurance Act of 1968, as amended (Title XIII of the Housing and Urban Development Act of 1968, P.L. 90-448), 42 U.S.C. 4001-4128, and 44 CFR Part 65. Pursuant to Section 1361 of the National Flood Insurance Act of 1968, as amended, communities participating in the NFIP are required to adopt and enforce floodplain management regulations that meet or exceed NFIP criteria. These criteria, including adoption of the FIS report and FIRM, and the modifications made by this LOMR, are the minimum requirements for continued NFIP participation and do not supersede more stringent State/Commonwealth or local requirements to which the regulations apply.

We provide the floodway designation to your community as a tool to regulate floodplain development. Therefore, the floodway revision we have described in this letter, while acceptable to us, must also be acceptable to your community and adopted by appropriate community action, as specified in Paragraph 60.3(d) of the NFIP regulations.

COMMUNITY REMINDERS

We based this determination on the 1-percent-annual-chance flood discharges computed in the FIS for your community without considering subsequent changes in watershed characteristics that could increase flood discharges. Future development of projects upstream could cause increased flood discharges, which could cause increased flood hazards. A comprehensive restudy of your community's flood hazards would consider the cumulative effects of development on flood discharges subsequent to the publication of the FIS report for your community and could, therefore, establish greater flood hazards in this area.

Your community must regulate all proposed floodplain development and ensure that permits required by Federal and/or State/Commonwealth law have been obtained. State/Commonwealth or community officials, based on knowledge of local conditions and in the interest of safety, may set higher standards for construction or may limit development in floodplain areas. If your State/Commonwealth or community has adopted more restrictive or comprehensive floodplain management criteria, those criteria take precedence over the minimum NFIP requirements.

We will not print and distribute this LOMR to primary users, such as local insurance agents or mortgage lenders; instead, the community will serve as a repository for the new data. We encourage you to disseminate the information in this LOMR by preparing a news release for publication in your community's newspaper that describes the revision and explains how your community will provide the data and help interpret the NFIP maps. In that way, interested persons, such as property owners, insurance agents, and mortgage lenders, can benefit from the information.

This determination is based on the flood data presently available. The enclosed documents provide additional information regarding this determination. If you have any questions about this document, please contact the FEMA Map Assistance Center toll free at 1-877-336-2627 (1-877-FEMA MAP) or by letter addressed to the LOMR Depot, 3601 Eisenhower Avenue, Alexandria, VA 22304. Additional Information about the NFIP is available on our website at http://www.fema.gov/nfip.

LETTER OF MAP REVISION
DETERMINATION DOCUMENT (CONTINUED)

We have designated a Consultation Coordination Officer (CCO) to assist your community. The CCO will be the primary liaison between your community and FEMA. For information regarding your CCO, please contact:

Mr. Carl L. Cook, Jr.
Director, Federal Insurance and Mitigation Division
Federal Emergency Management Agency, Region X
Federal Regional Center
130 228th Street Southwest
Bothell, WA 98021-9796
(425) 487-4682

STATUS OF THE COMMUNITY NFIP MAPS

We will not physically revise and republish the FIRM and FIS report for your community to reflect the modifications made by this LOMR at this time. When changes to the previously cited FIRM panel(s) and FIS report warrant physical revision and republication in the future, we will incorporate the modifications made by this LOMR at that time.

This determination is based on the flood data presently available. The enclosed documents provide additional information regarding this determination. If you have any questions about this document, please contact the FEMA Map Assistance Center toll free at 1-877-336-2627 (1-877-FEMA MAP) or by letter addressed to the LOMR Depot, 3601 Eisenhower Avenue, Alexandria, VA 22304. Additional Information about the NFIP is available on our website at http://www.fema.gov/nfip.

Kevin C Long

Kevin C. Long, CFM, Project Engineer
Engineering Management Section
Mitigation Division

CHANGES ARE MADE IN DETERMINATIONS OF BASE FLOOD ELEVATIONS FOR THE UNINCORPORATED AREAS OF WALLA WALLA COUNTY, WASHINGTON, UNDER THE NATIONAL FLOOD INSURANCE PROGRAM

On December 1, 1983, the Department of Homeland Security's Federal Emergency Management Agency identified Special Flood Hazard Areas (SFHAs) in the unincorporated areas of Walla Walla County, Washington, through issuance of a Flood Insurance Rate Map (FIRM). The Mitigation Division has determined that modification of the elevations of the flood having a 1-percent chance of being equaled or exceeded in any given year (base flood) for certain locations in this community is appropriate. The modified Base Flood Elevations (BFEs) revise the FIRM for the community.

The changes are being made pursuant to Section 206 of the Flood Disaster Protection Act of 1973 (Public Law 93-234) and are in accordance with the National Flood Insurance Act of 1968, as amended (Title XIII of the Housing and Urban Development Act of 1968, Public Law 90-448), 42 U.S.C. 4001-4128, and 44 CFR Part 65.

A hydraulic analysis was performed to incorporate improved topographic data along Reser and Russell Creeks and has resulted in a revised delineation of the regulatory floodways and increases and decreases in SFHA width for both Reser and Russell Creeks, increased and decreased BFEs for Russell Creek, and decreased BFEs for Reser Creek. The table below indicates existing and modified BFEs for selected locations along the affected lengths of the flooding source(s) cited above.

Location	Existing BFE (feet)*	Modified BFE (feet)*
Reser Creek:		
Just upstream of confluence with Russell Creek	938	937
Approximately 400 feet upstream of confluence with Russell Creek	941	940
Russell Creek:		
Just upstream of Powerline Road	927	928
Approximately 2,100 feet upstream of Powerline Road	941	940

*National Geodetic Vertical Datum, rounded to nearest whole foot

Under the above-mentioned Acts of 1968 and 1973, the Mitigation Division must develop criteria for floodplain management. To participate in the National Flood Insurance Program (NFIP), the community must use the modified BFEs to administer the floodplain management measures of the NFIP. These modified BFEs will also be used to calculate the appropriate flood insurance premium rates for new buildings and their contents and for the second layer of insurance on existing buildings and contents.

Upon the second publication of notice of these changes in this newspaper, any person has 90 days in which he or she can request, through the Chief Executive Officer of the community, that the Mitigation Division reconsider the determination. Any request for reconsideration must be based on knowledge of changed conditions or new scientific or technical data. All interested parties are on notice that until the 90-day period elapses, the Mitigation Division's determination to modify the BFEs may itself be changed.

Any person having knowledge or wishing to comment on these changes should immediately notify:

The Honorable David G. Carey
Chairman, Walla Walla County
Board of Commissioners
P.O. Box 1506
Walla Walla, WA 99362

Table of Contents

LIST OF TABLES ..... **viii**

LIST OF FIGURES ..... **ix**

ACKNOWLEDGEMENTS ..... **xi**

CHAPTER 1 INTRODUCTION TO VOLUME 2 ..... **1-1**

1.1 OVERVIEW OF VOLUMES 1 AND 2 ..... **1-1**
1.2 PURPOSE AND GOALS OF VOLUME 2 ..... **1-2**
1.3 SCOPE OF VOLUME 2 ..... **1-5**
1.4 DEVELOPING VOLUME 2 ..... **1-6**
1.5 HOW VOLUME 2 IS ORGANIZED **1-7**
1.6 HOW TO USE VOLUME 2 ..... **1-7**
1.7 USING SCIENCE TO PROTECT AND MANAGE WETLANDS **1-8**
1.7.1 Ecological Principles to Consider 1-9
1.7.2 Interpreting the Science 1-10
1.8 SCIENCE AND RISK MANAGEMENT **1-11**

CHAPTER 2 THE GROWTH MANAGEMENT ACT AND PROTECTION OF CRITICAL AREAS **2-1**

2.1 INTRODUCTION **2-1**
2.2 AN OVERVIEW OF THE GMA **2-1**
2.3 A REVIEW OF HEARINGS BOARD CASES AND COURT CASES **2-2**
2.3.1 Designating Critical Areas and Adopting Regulations to Protect Them 2-3
2.3.2 Relationship of Critical Areas Regulations to Other Land Uses 2-5
2.3.3 Including Best Available Science in Critical Areas Regulations 2-6
2.3.4 Protecting the Functions and Values of Critical Areas 2-8

CHAPTER 3 KEY CONCLUSIONS FROM VOLUME 1 ..... **3-1**

3.1 INTRODUCTION **3-1**
3.2 MAJOR CONCLUSIONS ABOUT OUR CURRENT EFFORTS TO PROTECT WETLANDS **3-1**
3.3 WETLANDS IN WASHINGTON AND HOW THEY FUNCTION (CHAPTER 2 OF VOLUME 1) **3-2**
3.3.1 Types of Wetland Functions and How They Are Controlled 3-2
3.3.2 Classification of Wetlands in Washington as a Key to Understanding Their Functions 3-3
3.4 ENVIRONMENTAL DISTURBANCES CAUSED BY HUMAN ACTIVITIES AND USES OF THE LAND (CHAPTER 3 OF VOLUME 1) **3-4**
3.5 NEGATIVE IMPACTS OF HUMAN DISTURBANCES ON THE FUNCTIONS OF WETLANDS (CHAPTER 4 OF VOLUME 1) **3-7**

3.6 THE SCIENCE AND EFFECTIVENESS OF WETLAND MANAGEMENT TOOLS (CHAPTER 5 OF VOLUME 1)..... 3-9
3.6.1 How Wetlands Are Defined..... 3-9
3.6.2 Wetland Buffers..... 3-10
3.7 THE SCIENCE AND EFFECTIVENESS OF WETLAND MITIGATION (CHAPTER 6 OF VOLUME 1)..... 3-11
3.7.1 Compliance of Projects with Permit Requirements (Volume 1 Section 6.4)..... 3-12
3.7.2 Ecological Effectiveness of Different Types of Compensation (Volume 1 Section 6.5)..... 3-12
3.7.3 Replacement Ratios (Volume 1 Section 6.6)..... 3-12
3.7.4 Functions and Characteristics of Mitigation Wetlands (Volume 1 Section 6.8)..... 3-13
3.7.5 Types of Wetlands Produced through Compensation Projects (Volume 1 Section 6.9)..... 3-13
3.7.6 Suggestions for Improving Compensatory Mitigation (Volume 1 Section 6.10)..... 3-14
3.8 CUMULATIVE IMPACTS TO WETLANDS AND THE NEED FOR A NEW APPROACH (CHAPTER 7 OF VOLUME 1)..... 3-14

CHAPTER 4 FRAMEWORK FOR PROTECTING AND MANAGING WETLANDS USING BEST AVAILABLE SCIENCE..... 4-1

4.1 INTRODUCTION..... 4-1
4.2 FOUR-STEP FRAMEWORK FOR PROTECTING AND MANAGING WETLANDS..... 4-2
4.2.1 Incorporating Different Geographic Scales in the Four-Step Framework..... 4-4
4.2.2 Step 1: Analyzing the Landscape and Its Wetlands (Landscape Analysis)..... 4-7
4.2.2.1 Analyses of the Contributing Landscape and the Management Area..... 4-7
4.2.2.2 Analyzing Wetlands at the Site Scale..... 4-8
4.2.3 Step 2: Prescribing Solutions..... 4-9
4.2.3.1 Prescribing Solutions at the Scale of the Contributing Landscape..... 4-9
4.2.3.2 Prescribing Solutions at the Scale of the Management Area..... 4-9
4.2.3.3 Prescribing Solutions at the Site Scale..... 4-10
4.2.3.4 Characterizing the Risk from Proposed Solutions..... 4-10
4.2.4 Step 3: Taking Actions..... 4-12
4.2.4.1 Taking Action at the Scale of the Contributing Landscape..... 4-12
4.2.4.2 Taking Action at the Scale of the Management Area..... 4-12
4.2.4.3 Taking Action at the Site Scale..... 4-13
4.2.5 Step 4: Monitoring..... 4-13
4.2.6 Adaptive Management..... 4-14

CHAPTER 5 ANALYZING THE LANDSCAPE AND ITS WETLANDS..... 5-1

5.1 INTRODUCTION..... 5-1
5.2 LANDSCAPE PROCESSES AND THEIR INFLUENCE ON WETLANDS AND THEIR FUNCTIONS..... 5-3
5.3 GOALS AND OBJECTIVES OF ANALYZING THE LANDSCAPE..... 5-5
5.4 QUESTIONS THAT CAN BE USED TO GUIDE AN ANALYSIS OF THE CONTRIBUTING LANDSCAPE AND THE MANAGEMENT AREA..... 5-6

5.4.1 Question 1. What are the landscape processes in the contributing landscape in the absence of human alterations, and where are they located geographically? 5-7
5.4.2 Question 2. What are the relationships between these original landscape processes and wetlands and their functions in the management area? 5-8
5.4.3 Question 3. What alterations to landscape processes have occurred, and how have these changes affected wetlands and their functions? 5-8
5.4.4 Question 4. What geographic areas are currently important for maintaining landscape processes and can be impacted by future activities and growth? 5-9
5.4.5 Question 5. What measures can be used to protect and restore landscape processes in order to protect and restore wetlands and their functions? 5-10
5.5 QUESTIONS THAT CAN BE USED TO GUIDE AN ANALYSIS OF INDIVIDUAL WETLANDS 5-10
5.5.1 Question 6. What wetlands are currently performing functions that are associated with important processes identified in the landscape analysis? .. 5-11
5.5.2 Question 7. What degraded wetlands or former wetlands are suitable for restoring landscape processes identified in Question 3? 5-11
5.5.3 Question 8. What are the functions of individual wetlands that need to be protected, preserved, or managed? 5-11

CHAPTER 6 PRESCRIBING SOLUTIONS: LANDSCAPE-BASED LAND-USE PLANS 6-1

6.1 INTRODUCTION 6-1
6.2 OVERVIEW OF PLANNING AND THE GMA 6-2
6.3 THE IMPORTANCE OF INCORPORATING A LANDSCAPE PERSPECTIVE IN PLANNING 6-4
6.4 SMART GROWTH 6-5
6.4.1 Smart Growth Can Be Used to Develop or Update Local Plans 6-7
6.4.2 Planning Approaches Using Smart Growth 6-8
6.4.3 Green Infrastructure Planning 6-9
6.4.3.1 The GRIST Approach 6-10
6.4.3.2 Implementing a GRIST Plan 6-12
6.4.3.3 Typical Steps for a GRIST Plan 6-12
6.4.4 Alternative Futures 6-17
6.4.4.1 Determining the Scope of the Analysis 6-17
6.4.4.2 Local Example of Alternative Futures Planning 6-21
6.4.5 Combining Complimentary Approaches 6-22
6.5 FISCAL SAVINGS AND OTHER BENEFITS 6-23
6.5.1 Using Green Infrastructure Instead of Constructing Infrastructure 6-23
6.5.2 Increase in the Local Tax Base 6-24
6.5.3 Reducing Costs of Public Services 6-25

CHAPTER 7 PRESCRIBING SOLUTIONS: COMPREHENSIVE PLANS 7-1

7.1 INTRODUCTION 7-1
7.2 AN OVERVIEW OF COMPREHENSIVE PLANNING 7-2
7.2.1 County-wide Plans and Policies 7-5

7.2.2 Tools for Implementing Comprehensive Plans 7-5
7.3 MANDATORY ELEMENTS OF COMPREHENSIVE PLANS 7-6
7.3.1 Land Use Element 7-6
7.3.1.1 Incorporating Landscape Analysis into the Land Use Element 7-7
7.3.1.2 Using Landscape Analysis in Different Sections of the Land Use Element 7-8
7.3.1.3 Landscape Analysis in the Policy Language of the Land Use Element 7-11
7.3.2 Capital Facilities Plan Element 7-17
7.3.3 Rural Lands Element 7-18
7.3.4 Transportation Element 7-19
7.3.5 Parks and Recreation Element 7-20
7.3.6 Economic Development Element 7-20
7.4 OPTIONAL ELEMENTS OF COMPREHENSIVE PLANS 7-20
7.4.1 Conservation Element 7-20
7.4.1.1 Natural Setting Element Used in Yakima County 7-21
7.4.2 Subarea Plans 7-22

CHAPTER 8 PRESCRIBING SOLUTIONS: REGULATORY TOOLS 8-1

8.1 INTRODUCTION 8-1
8.2 ISSUES IN ESTABLISHING REGULATIONS 8-4
8.2.1 Balancing Predictability with Flexibility 8-4
8.2.2 Staff Expertise and the Role of Third-Party Review 8-5
8.2.3 Separate Critical Area Permit vs. Provisions Throughout the Code 8-5
8.2.4 Risk Management for Wetland Resources 8-5
8.3 IMPORTANT ELEMENTS OF THE REGULATORY COMPONENT OF A PROTECTION PROGRAM 8-6
8.3.1 Designating, Identifying, and Mapping Wetlands 8-6
8.3.2 Applicability of Regulations 8-8
8.3.2.1 Protection of Wetlands Triggered by Various Development Permits 8-9
8.3.2.2 Separate Critical Area Permit 8-10
8.3.3 Exempted Activities, Allowed Activities, and Exceptions 8-11
8.3.3.1 Wetland Size 8-13
8.3.3.2 Size of Minimum Wetland Impact 8-14
8.3.3.3 Isolated Wetlands 8-14
8.3.3.4 Wetlands that are Prior Converted Croplands 8-14
8.3.3.5 Irrigation-Induced Wetlands 8-16
8.3.3.6 Clearing, Grading, and Placement of Fill 8-18
8.3.3.7 Ongoing Agriculture 8-18
8.3.3.8 Conversion of Wetlands to New Agriculture 8-19
8.3.3.9 Conversion of Agricultural Lands to Other Uses 8-19
8.3.3.10 Removal of Noxious Weeds 8-20
8.3.3.11 Forest Practices and Conversions 8-20
8.3.3.12 Removing Hazard Trees 8-21
8.3.3.13 Non-Compensatory Restoration and Enhancement 8-22
8.3.3.14 Stormwater Management 8-22
8.3.3.15 Emergency Activities 8-24

8.3.4 Wetland Rating 8-24
8.3.5 Requirements for Wetland Reports 8-25
8.3.6 Mitigation Sequencing 8-26
8.3.7 Compensatory Mitigation Requirements 8-26
8.3.7.1 Standards for Compensatory Mitigation 8-27
8.3.7.2 Special Types of Compensatory Mitigation 8-31
8.3.7.3 Impacts to buffers 8-36
8.3.8 Buffers 8-36
8.3.8.1 Issues Regarding the Regulation of Wetland Buffers 8-37
8.3.8.2 Reasonable Use Criteria 8-40
8.3.8.3 Buffer Averaging 8-41
8.3.8.4 Uses Within Buffers 8-41
8.3.8.5 Enhancement and Restoration of Buffer Areas 8-42
8.3.8.6 Best Management Practices to Enhance or Ensure Effective Functions of Buffers 8-43
8.3.8.7 Issues in Managing Buffers 8-44
8.3.8.8 Buffers in Urban Areas 8-46
8.4 MONITORING THE EFFECTIVENESS OF THE REGULATORY COMPONENT OF A PROTECTION PROGRAM 8-47

CHAPTER 9 PRESCRIBING SOLUTIONS: NON-REGULATORY TOOLS 9-1

9.1 INTRODUCTION 9-1
9.2 THREE CATEGORIES OF NON-REGULATORY ACTIONS TO CONSIDER 9-2
9.2.1 Preservation 9-3
9.2.2 Conservation 9-4
9.2.3 Restoration 9-4
9.3 FISCAL BENEFITS OF USING NON-REGULATORY TOOLS 9-5
9.4 IMPORTANT CONSIDERATIONS WHEN INCORPORATING NON-REGULATORY TOOLS 9-6
9.4.1 Funding Mechanisms 9-7
9.4.1.1 Common Forms of Conservation Revenue in Washington 9-9
9.4.1.2 Land Banking 9-9
9.4.2 Landowner Incentives 9-10
9.4.2.1 Incentive-based Tools: Open Space Current Use Taxation 9-10
9.4.2.2 Other Incentive-Based Tools 9-11
9.4.3 Incentive Zoning and Regulation 9-12

CHAPTER 10 PRESCRIBING SOLUTIONS: CHARACTERIZATION OF RISKS 10-1

10.1 INTRODUCTION 10-1
10.2 RISK AND THE GROWTH MANAGEMENT ACT 10-2
10.3 A PROCESS FOR CHARACTERIZING RISKS 10-4
10.3.1 Identifying the Environmental Disturbances or Benefits that Result from Proposed Actions 10-5
10.3.2 Identifying the Risks of Disturbances to the Functions and Values of Wetlands 10-6

10.3.3 Proposing Measures to Minimize the Risk or Replace the Resource at Risk…. 10-7

CHAPTER 11 TAKING ACTIONS: REGULATORY AND NON-REGULATORY ACTIVITIES 11-1

11.1 INTRODUCTION 11-1
11.2 IMPLEMENTING THE REGULATORY COMPONENT OF A PROTECTION PROGRAM 11-2
11.2.1 Adequately Trained Staff or Qualified Wetland Professional 11-2
11.2.2 The Process for Reviewing Permits 11-3
11.2.3 Inspecting and Monitoring the Wetland During Construction 11-4
11.2.4 Enforcing Regulations 11-4
11.2.5 Monitoring the Effectiveness of Regulations 11-5
11.2.6 Educational Materials 11-5
11.3 IMPLEMENTING THE NON-REGULATORY COMPONENT OF A PROTECTION PROGRAM 11-5
11.3.1 Staffing the Non-Regulatory Component 11-6
11.3.2 Identifying, Mapping, and Prioritizing Sites 11-7
11.3.3 Creating Partnerships for Locally Sponsored Projects 11-7
11.3.4 Identifying a Recipient to Hold and Manage Land or Rights to Land 11-8
11.3.5 Establishing Funding Mechanisms and Incentives for Landowners 11-8
11.3.6 Educating and Involving the Public 11-9
11.3.7 Monitoring Preservation and Restoration 11-9

CHAPTER 12 MONITORING AND ADAPTIVE MANAGEMENT 12-1

12.1 INTRODUCTION 12-1
12.2 WHAT SHOULD BE MONITORED? 12-3
12.2.1 Monitoring Trends in the Resource 12-3
12.2.2 Monitoring the Implementation of Protection Measures 12-4
12.2.2.1 Monitoring Implementation at the Scale of the Contributing Landscape 12-5
12.2.2.2 Monitoring Implementation at the Scale of the Management Area 12-5
12.2.2.3 Monitoring Implementation at the Site Scale 12-6
12.3 ADAPTIVE MANAGEMENT 12-6

Acknowledgements

As with Volume 1, a great effort was put forth to complete this volume. A huge thank you is extended to the authors and Core Team members who spent many hours discussing, writing, and re-writing the public review draft as well as the final, some working after hours and on weekends. They deserve great kudos for their patience during the many rounds of edits that took place.

A special acknowledgement goes to Sara Noland of 2N Publications and Dyanne Sheldon of Sheldon and Associates for their work on the draft. Both went beyond the "call of duty" writing, reviewing and editing text while attending to their other demanding responsibilities. Sara had the patience of a saint as she edited text from multiple authors and incorporated Core Team comments throughout the process. Tom Noland of 2N Publications also lent his creative technical support during the production of the draft.

The team of local government staff that advised the Core Team during the development of the draft document are also acknowledged. The Local Government Wetland Advisory Team met numerous times to discuss complex and heated issues and provided invaluable suggestions and perspectives.

Steve Penland from the Washington State Department of Fish and Wildlife is commended for his responsiveness and collaboration on various iterations of this volume, as is Katherine March for her participation on the Core Team and Bob Ziegler for his review comments. Thanks to Michael Rylko from U.S. Environmental Protection Agency for lending his expertise on landscape-based land-use plans.

Tom Hruby of the Washington State Department of Ecology went beyond the call of duty to gladly work on any task asked of him even if they involved chapters not of his authorship. Thank you also to Erik Stockdale for his pain-staking work on the reference list and glossary.

Thank you to Susan Grigsby of Ecology for her responsiveness and technical assistance related to landscape analysis. Ecology staff Yolanda Holder and Paige Boulé are both acknowledged for their ready willingness to finalize and proof files; checking spelling, formatting, pagination, and reading the text from the standpoint of a non-expert. Donna Bunten of Ecology assisted with proofing the copy-ready version. Thank you to Tim Schlender of Ecology for working on the covers and assisting with the development of the web site and posting of the documents on the site.

Dana Mock of Ecology must be praised greatly and thanked profusely for her dedication, persistence, thoroughness, and patience during the completion and distribution of the final document. The project could not have been completed (nor would it have been as much fun) without her.

Special kudos also to Teri Granger for again managing an overwhelming project with aplomb. Working with an advisory team, multiple authors, and the support staff needed to

produce a coherent guidance document (as well as writing and editing) is akin to herding cats; tasks Teri does with patience, skill, and tact.

Andy McMillan must be applauded for his inspiration regarding the entire project and the production of both volumes. He served as the wise leader and creative problem-solver for all aspects of the project, and he is a good writer to boot. In addition, as noted in Volume 1, he obtained funding for the project from several sources. In the most literal sense, the project would never have happened nor been successful without his extensive knowledge, skills, and experience. In this sense, this tome is his.

The U.S. Environmental Protection Agency provided the primary financial backing for Volume 2 as it did for Volume 1. The Washington Department of Ecology also contributed funding for this volume. As with Volume 1, we thank the agencies for their support in undertaking such an ambitious endeavor.

Chapter 1
Introduction to Volume 2

1.1 Overview of Volumes 1 and 2

This document is the second in a two-volume series addressing wetlands in Washington and their protection and management. The first volume, *Freshwater Wetlands in Washington State - Volume 1: A Synthesis of the Science* (Sheldon et al. 2005), is a synthesis of the most current science and was released in draft form to the public in the fall of 2003. The comments from reviewers of the draft were used to revise the document and create the final version. All of the comments received on Volume 1 and the author's responses to them, as well as a 10-page summary of the significant comments, are posted on the project's web page: http://www.ecy.wa.gov/programs/sea/bas_wetlands.

Volume 1 synthesized the literature regarding:

- Freshwater wetlands in Washington and how they function
- The effects of human activities on Washington's freshwater wetlands and their functions
- The tools used to protect and manage freshwater wetlands and their functions and values

The key conclusions from Volume 1 are summarized in Chapter 3 in this document.

Volume 2 contains guidance primarily for local governments on protecting and managing wetlands and their functions based on the synthesis of the science in Volume 1. Although the primary audience is local governments, the information contained in this document should be useful to anyone who has an interest in the protection and management of wetlands in the state.

The key themes or messages in Volume 2 are as follows:

- By relying on a site-by-site approach to managing wetlands, we are failing to effectively protect them
- To effectively protect wetlands and their functions, we must understand and manage their interaction with the environmental factors that control wetland functions
- To understand and manage these environmental factors and wetland functions, information generated through landscape analysis is needed

- Landscape analysis should be one step in a four-step framework that should be used in developing a diversified program to protect and manage wetlands and their functions; the four-step framework should include analyzing the landscape, prescribing solutions, taking actions, and monitoring results and applying adaptive management

- Protection and management measures developed and implemented in steps two and three of the four-step framework (prescribing solutions and taking action) should incorporate a full range of components including:

  – Policies and plans such as landscape-based plans (such as Green Infrastructure), comprehensive plans, subarea plans, etc.

  – Regulations such as critical areas ordinances, clearing and grading ordinances, etc.

  – Non-regulatory activities such as incentives that encourage conservation, restoration, and preservation through voluntary efforts

1.2 Purpose and Goals of Volume 2

Both Volumes 1 and 2 were written to assist local governments in complying with requirements in the Growth Management Act (GMA) to include the best available science when adopting development regulations to designate and protect critical areas, including wetlands. The GMA requires that local governments protect wetland functions and values, and evaluate and include relevant scientific information when determining what policies, plans, and regulations are needed. (See Chapter 2 for a discussion of the relevant mandates in the Growth Management Act.)

This is a challenging task and one that some cities and counties are poorly equipped to undertake. Many local governments have asked the state departments of Ecology and Fish and Wildlife to assist them by synthesizing the science (Volume 1) and providing general guidance as well as specific recommendations for protecting wetlands based on the science (Volume 2). (See Section 1.4 on how Volume 2 was developed.)

The guidance presented in Volume 2 is advisory only. Local governments are not required to use this guidance. The guidance in and of itself is not "best available science." Rather, it represents the recommendations of the departments of Ecology and Fish and Wildlife as to how a local government could include the best available science in policies, plans, and regulations to protect wetlands.

Volume 2 was also written to address the fact that wetlands continue to be lost and degraded through human activities in spite of the adoption of "no net loss" policies at local, state, and federal levels and an increased knowledge of the complex processes that drive wetland functions. The results of the scientific research synthesized in Volume 1 are clear: We have not stopped the continued degradation of our wetlands and their functions (Sheldon et al. 2005).

As concluded in Volume 1, wetland losses often result from a combination of impacts from human activities that occur both within and outside individual wetlands. Changes from human activities result in cumulative impacts across the landscape. Currently, however, the majority of decisions about managing wetlands in Washington State fail to consider environmental factors that control wetland functions or the consequences of human actions that occur at a landscape scale; they are made on a case-by-case basis related to specific projects.

The departments' goals for Volume 2, therefore, are to help local governments:

- Include current scientific information in their decisions about the protection and management of wetlands to meet the requirements of the GMA
- Incorporate a diversified, landscape-based approach to better protect wetlands and their functions and values and to manage cumulative effects

Where possible, the authors of Volume 2 provide several options for protecting and managing wetlands using landscape analysis, processes for planning, regulatory options, as well as non-regulatory approaches. For example, three alternatives for buffer widths are presented, one being a matrix using factors such as wetland rating, intensity of the proposed, adjacent land use, wetland functions, and other characteristics. Such approaches allow more flexibility.

In the future, it is hoped that:

- The protection and management of wetlands will be integrated with the management of all environmental resources across the landscape
- Impacts to wetland functions and values from decisions about land uses will be understood at the appropriate geographic scales
- Local jurisdictions will plan for future development in a proactive manner, so impacts to the environmental factors that control functions are minimized before they occur
- When tradeoffs between conflicting values are made, the decision will be made with a full understanding of the "true value" lost or gained

1.2.1 Implementing a More Comprehensive Approach

This volume presents a four-step framework that integrates scientific information about the landscape (landscape analysis), planning approaches, and regulatory and non-

regulatory actions at the different geographic scales at which natural resources should be managed. It represents the ideal situation where a local government has adequate resources and commitment to undertake this process. The available scientific information makes clear that the most effective way to protect wetland functions and values is to use a comprehensive, landscape-based approach. Addressing only some of the recommendations in this volume, therefore, increases the risk that wetland functions and values will not be adequately protected. (See Chapter 10 for additional discussion of characterizing the risk of proposed solutions for protecting and managing wetlands.)

The departments of Ecology and Fish and Wildlife understand that not all local governments are currently in a position to implement the diversified, comprehensive program described in Volume 2. The entire process is presented so users can understand what information or tasks they are missing and to help understand the tradeoffs being made and the risks taken.

The authors of Volume 2 also recognize that many jurisdictions will face a challenge in updating their development regulations to meet the state GMA deadlines, even without incorporating a landscape perspective at this time. In addition, transforming our approach to managing wetlands from a site-specific focus to a view of the broader landscape is a change of practice for local governments. It will most likely occur incrementally as local governments collect and analyze landscape data and incorporate that information into their various policies, plans, and regulatory and non-regulatory activities. Local governments, therefore, should at a minimum adopt strong wetland regulations until they can incorporate landscape-based plans, policies, and non-regulatory elements.

Working with local governments on developing and using landscape analysis

This document provides ideas on how to analyze the landscape as well as references for the various analyses that are available (see Chapter 5 and Appendix 5-B). One method for landscape analysis that is described is a method currently being developed by Ecology. It provides suggestions on how to analyze landscape information (such as geology, soils, and water flow) for use in planning, developing protection measures, and identifying wetlands for restoration and preservation.

Ecology's method for landscape analysis is being improved as it is applied in different jurisdictions. In addition, the methods are currently lacking an analysis of wildlife habitat and corridors. This gap will be addressed in the near future as the departments of Fish and Wildlife and Ecology work together to better include wildlife factors in the analysis.

Ecology invites local governments to work with the agency to conduct landscape analyses and use the information to develop more effective approaches to protecting and managing the landscape and its wetlands. In this way, local governments can play an important role in further developing this approach to landscape analysis.

1.3 Scope of Volume 2

1.3.1 Non-GMA Protection of Wetlands is Not Addressed in Volume 2

The regulations and management programs implemented by federal, state, and tribal governments are not discussed in Volume 2. For example, the Clean Water Act administered by the U.S. Army Corps of Engineers is not discussed. These laws are only mentioned in relation to direct mandates to local governments. For example, the definition of wetlands used by local governments is mandated in state statute (see Chapter 8).

There is, however, a brief discussion of the Shoreline Management Act (SMA). In Chapter 4, the SMA is mentioned in relation to the four-step framework recommended in this volume for local wetland protection programs. The SMA guidelines include requirements for the inventory and analysis of "ecosystem-wide processes" (landscape processes). These requirements are consistent with the recommendations in Volume 2 for incorporating landscape analysis into local planning and protection efforts. The reader is referred to the following web site more information on the SMA guidelines (http://www.ecy.wa.gov/programs/sea/SMA/index.html).

1.3.2 Vegetated Tidal Wetlands are Addressed in Volume 2

The recommendations made in this document are not strictly limited to freshwater wetlands. Vegetated tidal wetlands (a subset of all tidal wetlands including vegetated wetlands in estuaries and coastal lagoons) are addressed specifically in the revised wetland rating system for western Washington (Hruby 2004b) because they were included in past versions of the rating system, even though the scientific information about them was not summarized in Volume 1. The scientific information on which recommendations for tidal wetlands were based is summarized in Appendices 8-E and F.

1.3.3 How Values are Addressed in Volume 2

As discussed in Volume 1, wetland functions are the things that wetlands "do." Society, however, does not necessarily attach "value" to all wetland functions. Value is usually associated with goods and services that society recognizes. For example, trapping sediments is a wetland function that improves water quality, and this is often valued by society. Not all of the environmental factors that control wetland functions or the functions themselves, however, are recognized or valued.

Sometimes what is valued is not what a wetland does but some other aspect of the wetland ecosystem that is considered important socially. For example, "recreation" is valued by society and is often called a function even though it is not something a wetland "does." Other aspects of the wetland ecosystem that are valued and have been called

functions include "education" and "aesthetic quality." These values are sometimes referred to as *social functions* to separate them from functions based on environmental factors.

The social functions cannot be assessed or rated using the same methods used to assess functions based on environmental factors. Valuing social functions requires methods based on economic, sociologic, and psychological tools, rather than on ecology and other environmental sciences. Therefore the literature on social functions was not synthesized in Volume 1.

The values of a community are an important consideration when developing the plans and polices of local governments. Values in this context are opinions held by communities in regard to what is important to them. For example, a community (urban or rural) might value one wetland function more than another. Water quality improvement might be more valued than flood control in an area with water quality problems if that community is not in an area prone to flooding. In addition, a community might value certain amenities in their neighborhoods or rural areas above others. For example, a neighborhood might value keeping the maximum amount of vegetated area through clustered development as opposed to scattered development that results in fragmented islands of vegetation. The need to identify and consider these values is discussed in Chapters 6 and 7. The landscape analysis discussed in Chapter 5 provides important information needed when making decisions about a community's values as well as what communities, and their wetlands, will be like in the future.

1.4 Developing Volume 2

Production of this document and Volume 1 was funded through a grant from the U.S. Environmental Protection Agency. Attendees of two focus groups provided early direction for the volumes. Meetings of focus groups were held in Olympia and Moses Lake in early 2002 to solicit ideas for the scope and objectives of the project. This information was used to guide the development of both volumes. These focus groups were attended by over 60 individuals, primarily representatives from local governments and consulting firms.

Both volumes were developed by a team (called the Core Team). Membership of the Core Team changed somewhat with the initiation of Volume 2. The Core team for Volume 2 consisted of staff from the departments of Ecology, Fish and Wildlife, and Community, Trade and Economic Development; Sheldon & Associates; and 2N Publications (the contract editor for the draft). A list of the members of the Core Team for Volume 2 is provided in Appendix 1-A. Several members of the Core Team wrote the various sections, chapters, and appendices of Volume 2.

The Core Team developed the guidance in conjunction with a team of local government staff: a Local Government Wetlands Advisory Team (LGWAT). The LGWAT members are also listed in Appendix 1-A. The LGWAT convened in December 2003 to provide ongoing input and guidance during the development of this volume. The team met

several times to review and respond to draft concepts and materials developed by the Core Team. Additionally, meetings were held with representatives from the business and environmental communities to solicit their ideas and comments on concepts and early draft documents (see Appendix 1-B).

The draft of Volume 2 was distributed for review during a four-week period to solicit comments. It was provided to all those who requested a hard copy, or a CD, or who downloaded it from the project's web page. Prior to the completion of the draft, a newsletter was sent to the project's mailing list of over 1,200 recipients, informing them of the review period. They were requested to inform Ecology if they wanted to review the draft and in what form they wanted to receive it. The Core Team requested that reviewers critique the general guidance as well as specific recommendations or additions. Comments regarding organization and ease of reading were also welcomed.

Seven reviewers provided comments (see Appendix 1-B) which were reviewed by the authors and were compiled in a separate document along with the author's responses to the comments. All four documents (responses to comments on the draft of Volume 1, the final version of Volume 1, responses to comments on the draft of Volume 2, and the final version of Volume 2) are posted on the project's web page and can be obtained as a CD or paper copy (http://www.ecy.wa.gov/programs/sea/bas_wetlands).

1.5 How Volume 2 is Organized

Volume 2 is organized into 12 chapters plus references, a glossary, and appendices. The first three chapters in this document explain the purpose, legal basis, and basic scientific foundation for the recommendations that follow. Chapter 4 outlines a suggested framework (divided in to four steps) which local governments can use to develop a diversified program to protect and manage wetlands. The remaining chapters, Chapters 5-12, describe the four steps and the primary components of a wetland protection program. The chapters include discussions of analyzing the landscape, landscape-based plans, comprehensive plans, regulatory and non-regulatory tools, characterizing the risk of wetland protection, implementing components of a protection program, and monitoring and adaptive management. Methods for analyzing landscapes and wetlands, recommended language for an ordinance, and various supporting information are provided in the appendices.

1.6 How to Use Volume 2

Local governments are encouraged to read and understand the entire document before determining how they want to protect wetland functions and values. This document is not intended to be a scientific treatise and, in general, references to specific scientific literature are limited. While Chapter 3 provides an overview of the scientific basis for the recommendations in this document, the more detailed, peer-reviewed and referenced information on wetland science is contained in Volume 1. We highly recommend reading Volume 1 as well, especially key points and conclusions.

As noted above, many of the recommendations in this document cannot be tied to a specific scientific article and cannot be cited as such (or the list of citations would be extremely long and cumbersome). Citations are provided only when a specific recommendation was also made within the scientific literature. Additional literature sources are cited in Chapters 6, 7, 9 and elsewhere in various parts of Volume 2. Many of these are more oriented towards policy and are not strictly scientific in nature. They were not, therefore, included in the synthesis of the science in Volume 1. Lastly, references are provided in various appendices. These are not necessarily included in the list of cited references but are at the end of the individual appendix in which they are mentioned.

In Volume 2, measurements are given in English Customary instead of metrics, whereas in Volume 1 both metric and standard are provided. For example, buffer widths are listed in feet only, not feet and meters. This was chosen because most local governments use English Customary measurements in their plans and regulations.

As mentioned previously, the guidance provided in Volume 2 is advisory only. The Growth Management Act <u>does not</u> require that local governments adopt the protection measures recommended in this document. Local governments are free to use or adapt the four-step framework and the options and recommendations presented here or develop entirely different approaches to protecting wetlands to fit their particular circumstances.

1.7 Using Science to Protect and Manage Wetlands

We recognize that it is challenging for local governments to include the best available science in developing or updating measures to protect and manage wetlands. In the following sections we discuss several topics relevant to this challenge. The topics include ecological principles to use when considering options for protecting and managing wetlands, some reasons why including the science can be challenging, and understanding the risks of the decisions made.

"To be effective, the nation's wetlands protection and management programs must anticipate rather than react. They should focus on future, not the present or the past; on effectively protecting the remaining resources and actively restoring or creating additional wetlands. They should anticipate needs and problems on the basis of rigorous analyses of regional resources, trends, stresses, and values. They should consider the whole, not just the individual parts."

The Conservation Foundation, *Protecting America's Wetlands: An Action Agenda. The Final Report of the National Wetlands Policy Forum* (1988).

1.7.1 Ecological Principles to Consider

The Ecological Society of America has taken a lead in compiling and explaining scientific principles on managing natural resources, such as wetlands (Dale et al. 2000). The ecologist's goal is to ensure that future decisions include the best scientific information available. The principles illustrate the need to take a more holistic, landscape approach to managing our natural resources. The principles and their implications in environmental decision making are briefly summarized in Table 1-1.

Table 1-1. Ecological principles and their implications in making decisions about land use (adapted from Dale et al. 2000 to focus on wetlands rather than land use in general).

Ecological Principle	Implication for Managing Land Use in and Around Wetlands
The type, intensity, and duration of disturbances are the major factors shaping populations and the ecosystem as a whole. Disturbances can occur at many different spatial and temporal scales.	Changes in land use that cause new disturbances are likely to cause changes in animal and plant populations and the functions of a wetland. We need to manage disturbances at the scale at which they occur. For example, the eutrophication of a wetland may be a result of disturbances throughout its watershed and this problem cannot be managed only within the wetland itself. Also, it is not possible to target a specific "end point" when creating or restoring wetlands because changes are continuous.
Ecological processes operate at many time scales, and ecosystems change through time.	The current state of a wetland is in part a consequence of historical conditions. Therefore, historical information may be needed to understand how a wetland will respond to disturbance. Managing wetlands to protect their valuable functions requires us to consider how ecological processes change through time both with and without the influence of human activities.
Some species have key, broad-scale effects on the ecosystem (keystone species).	The removal of keystone species can radically change the functions in a wetland and spread well beyond the boundaries of the wetland. Because the effects of keystone species are complicated and not fully understood, we cannot predict the effects on the ecosystem of changes in their numbers or distribution. For example, removing beavers from a river system has significant impacts on the biological diversity and flooding patterns of the entire watershed.
Local conditions strongly affect environmental functions at a site.	The position of a wetland in the landscape defines the functions it performs. Wetlands in a specific landscape position may perform only certain functions and at specific rates. We need to understand these local conditions when creating, restoring or enhancing wetlands so we do not "plan" for functions that the landscape will not support. For example, wetlands on slopes do not pond water. Creating a ponded wetland on a slope is not compatible with the position in the landscape, and maintaining this wetland will require constant management of the dikes and the outflow structure.
The size, shape, and location of different types of uplands around a wetland influence its functions.	An understanding of the surrounding landscape is needed to understand the implications of decisions made about an individual wetland.

The Ecological Society of America has also proposed guidelines for managers to use in considering the ecological impacts of their decisions about land use (including wetlands) (Dale et al. 2000). These guidelines, listed below, can be considered a checklist of factors to consider when making decisions about protecting or managing wetlands:

- Examine the impacts of local decisions in a regional (or landscape) context
- Plan for long-term change and unexpected events
- Preserve rare landscape elements, critical habitats, and associated species
- Avoid land uses that deplete natural resources over a broad area
- Retain large contiguous or connected areas that contain critical habitats
- Minimize the introduction and spread of non-native species
- Avoid or compensate for the effects of development on ecological processes
- Implement land use and land management practices that are compatible with the natural potential of the area

1.7.2 Interpreting the Science

Decisions by hearings boards and the courts have made clear that the requirement to "include the best available science in developing policies and development regulations to protect the functions and values of critical areas" is a substantive requirement, not merely a procedural one. (A review of hearings board and court cases that summarizes the key findings related to best available science, prepared by staff from the Department of Community, Trade and Economic Development and the state Attorney General's office, is presented in Chapter 2.)

However, incorporating scientific information in policies, plans, and regulations is challenging. The science of projecting how future land uses influence aquatic resources, such as wetlands, is still in its infancy (Nilsson et al. 2003). Planners using the scientific information available should not expect to be able to employ detailed methods that provide quantitative assessments of impacts from future development. Using existing data and tools, the ecological forecasts are largely qualitative in nature and essentially based on expert knowledge and correlations (Nilsson et al. 2003). Thus, the results of applying scientific principles are presented in terms of a "high," "moderate," or "low" risk to natural resources rather than a quantitative estimate of impacts (e.g., the number of amphibian species will be reduced by 50% if the county permits the filling of 10% of the remaining wetlands).

In fact, one of the greatest difficulties in applying scientific information in land-use planning and management is that the "science" doesn't provide specific answers for each circumstance that arises. The scientific information available rarely supplies us with exact or precise solutions for local circumstances. For example, some experiments that could be used to estimate the loss of amphibian species may not be applicable outside the immediate geographic area where the experiments were performed.

Furthermore, the scientists who reviewed the literature for Volume 1 found few studies that actually documented the effectiveness of specific protection measures (see Chapters 5 and 6 in Volume 1). Rather, most studies discuss the impacts of human activities on wetlands in general. The results are presented as correlations. For example, a decline in amphibian species in the Stockholm Sweden area has been correlated with the amount of developed land in the immediate vicinity of wetlands (Lofvenhaft 2002). This type of study does not demonstrate a true cause-and-effect relationship. There is no experimental proof that the decline is caused by the change in land use. Many impacts of human activities are not well understood and can only be hypothesized based on correlations.

As a result, recommendations based on scientific information are, to a large degree, based on hypotheses that extrapolate and synthesize all the information collected. Many of the recommendations in this document represent the collective interpretations by the authors (as reviewed by the Department of Fish and Wildlife) of the findings of the scientific literature synthesized in Volume 1 and how it pertains specifically to Washington or specific geographic regions within the state.

For example, the recommendation that a 200-foot buffer will adequately protect the wildlife habitat functions of high-functioning wetlands in eastern Washington is not based on one specific scientific study. Rather, it represents a synthesis of many studies (see Chapter 5 in Volume 1). These studies show that different species need different widths of buffers that range from 100 feet to more than 600 feet. Furthermore, very few studies have focused specifically on the needs of wildlife in wetlands of eastern Washington. Therefore, to provide general guidance, the authors were forced to make an informed decision on the size of buffer needed to protect wildlife in the wetlands of eastern Washington. In the absence of information about the species actually using a wetland, it was judged that a 200-foot buffer would adequately protect wildlife in wetlands that provide good habitat and are well connected in the landscape with a moderate risk that the protection standard will result in some degradation or loss of function. A local jurisdiction that wants to take a low-risk approach would increase the buffer widths above what is recommended in this volume.

1.8 Science and Risk Management

One of the major recommendations made in Volume 2 is that local jurisdictions should understand the risk to the wetland resource resulting from their decisions. The uncertainties of translating the science to specific protection measures, described above, is one of the reasons that local governments need to assess the risks. Using buffers again as an example, one might ask: *How wide a buffer is enough to protect wetland functions?* The science does not say that a 100-foot buffer will protect a certain kind of wetland, whereas a 95-foot buffer will not. Instead, scientific information on buffers clearly states that buffers are important, that they perform many functions that are critical to maintaining wetland functions, and that a wide range of buffer widths provides a variety of benefits depending on a number of factors.

Therefore, answering the critical question *How wide a buffer is enough?* is largely an exercise in assessing the science and deciding how much risk is acceptable. A regulation that sets a 300-foot buffer around every wetland significantly reduces the risk to those wetlands from human activities in the immediate vicinity of the wetland. That regulation can be characterized as relatively "low risk." On the other hand, a jurisdiction that decides they will provide a 50-foot buffer for all wetlands would have to characterize their action as "high risk" because a 50-foot buffer will not protect many wetland functions.

In this document, risk is addressed by tailoring the degree of protection to several factors that the scientific literature says are important. Continuing to use buffers as an example, one option presented in Volume 2 provides different buffer widths depending on the type of wetland and the functions it performs, as well as the type and intensity of adjacent land use. The widths recommended in this volume were selected from the middle of the range of buffers suggested in the literature: This, therefore, represents a moderate risk approach to determining buffer widths.

"Characterizing the risk" of decisions is also an important tool for improving approaches to wetland protection. Scientific data on the effectiveness of measures for protection can be collected and used to monitor the success of wetland management. This information then provides an objective basis on which to revise management approaches. (Risk characterization is discussed in detail in Chapter 10, and Chapter 12 provides information on monitoring and adaptive management.)

Many local governments will be inclined to rely largely on a regulatory approach to protect wetlands, and will tend to skip over the guidance on using a landscape approach as well as recommendations regarding landscape-based plans and non-regulatory tools. However, we believe the key message from the scientific literature is that reliance upon a strictly regulatory, permitting approach will fail to adequately protect wetland functions and values. Decision-makers should, therefore, consider the entire context of wetland protection and management when choosing the protections afforded to wetlands — from reducing impacts to wetlands through planning and zoning based on landscape analysis to using non-regulatory approaches such as stewardship incentives and restoration programs.

Chapter 2

The Growth Management Act and Protection of Critical Areas

2.1 Introduction

This chapter provides background on the Washington State Growth Management Act (GMA) and its directives to local governments to protect critical areas such as wetlands. It also clarifies issues regarding the protection of critical areas and incorporation of best available science into critical areas regulations.

> As defined in Chapter 36.70A.030(5) Revised Code of Washington (RCW), "critical areas" include: wetlands; areas with a critical recharging effect on aquifers used for potable water; fish and wildlife habitat conservation areas; frequently flooded areas; and geologically hazardous areas.

2.2 An Overview of the GMA

In 1990, the Washington State Legislature passed the GMA (RCW 36.70A) to guide local jurisdictions in their decisions regarding land use. The GMA dictates that counties and cities with certain characteristics must plan for future growth (RCW 36.70A.040). The GMA (RCW 36.70A.020 and RCW 90.58.020) identifies 14 goals that are to be used by local governments to "guide" the development of comprehensive plans and development regulations, including critical areas ordinances, to meet its intent and requirements. The goals consist of a range of actions, including concentrating urban development to reduce sprawl, providing a range of affordable housing, ensuring that transportation infrastructure is coordinated between jurisdictions, and assuring property rights.

In addition, the GMA includes goals that address maintaining the extraction of natural resources, such as timber and mining, and agricultural land uses while avoiding incompatible uses; providing for open space and recreation, including conserving fish and wildlife habitats; and protecting the environment and the quality of life in the state. Cities and counties have responded to these mandates by developing or updating their comprehensive plans and development regulations.

The GMA requires jurisdictions to develop regulations that implement their comprehensive plan provisions (RCW 36.70A.040). Comprehensive plans and development regulations, including critical areas regulations, are subject to continuing review and evaluation by the county or city that adopted them. In 2002, the Legislature

amended the GMA to require counties and cities to take legislative action to review and, if needed, revise their comprehensive land-use plans and regulations on a seven-year cycle to ensure the plans and regulations comply with the requirements of GMA (RCW 36.70A.130). (The review cycle had previously been five years.)

The GMA also requires local jurisdictions to include the best available science in the development of policies and development regulations used to both designate and protect the functions and values of critical areas (RCW 36.70A.172). The Legislature considered the requirement for best available science an important step toward regulatory reform and timely permitting of projects.

The GMA contains a variety of provisions that are directly related to landscape-based planning and developing regulations based on science. For example, there is a requirement to identify open space corridors within and between urban growth areas (RCW 36.70A.160). In addition, the GMA states that the corridors are to provide lands that are "… useful for recreation, wildlife habitat, trails, and connection of critical areas as defined in RCW 36.70A.030." This provision relates to one of the key findings of the synthesis of the science in Chapter 3 of Volume 1, which identifies habitat fragmentation (elimination of habitat links between wetlands) as one of the significant, adverse effects of urbanization on biodiversity. Other examples include provisions under the land use element (RCW 36.70A.070(1)) which requires the "protection of the quality and quantity of groundwater used for public water supplies" and, where applicable, the review of "drainage, flooding, and storm water run-off in the area and nearby jurisdictions and provide for guidance for corrective actions to mitigate or cleanse those discharges that pollute waters of the state, including Puget Sound, or waters entering Puget Sound."

In passing the GMA, the Legislature also required that local governments coordinate their comprehensive plans with jurisdictions that share either common borders or regional issues, to be consistent across political boundaries. Variations in zoning regulations, density of housing, for example, as well as the infrastructure built for transportation, water service, sewage, and other necessary public utilities, had been resulting in inconsistent and incompatible uses and expectations across jurisdictional boundaries.

2.3 A Review of Hearings Board Cases and Court Cases

The following sections present a review of court cases and Growth Management Hearings Board cases prepared by Alan Copsey, Washington State Attorney General's Office, and Chris Parsons, Washington State Department of Community, Trade and Economic Development. The text in these sections is from a memorandum (dated April 2004) to state agencies developed by Chris Parsons, summarizing Alan Copsey's information about GMA and critical areas protection. Minor edits have been made to the formatting of this text, such as the addition of subheadings, and to punctuation to make it consistent with the format of other chapters in this volume.

2.3.1 Designating Critical Areas and Adopting Regulations to Protect Them

The GMA recognizes that the first formal step required in implementing the GMA is the designation and protection of critical areas. This is important for two reasons: 1) to exclude critical areas from urban growth designations and impacts, and 2) to prevent irreversible environmental harm while comprehensive plans and implementing development regulations are prepared.

All three Growth Management Hearings Boards in Washington State (Central Puget Sound, Eastern Washington, and Western Washington) have recognized and given effect to the required priority of critical areas designation and protection.[1] The phrase *given effect to* implies a legal review and decision conferring status. In an oft-quoted passage, the Central Board explained:

> *It is significant that the Act required cities and counties to identify and conserve resource lands and to identify and protect critical areas before the date that IUGAs had to be adopted. This sequence illustrates a fundamental axiom of growth management: "the land speaks first." Only after a county's agricultural, forestry and mineral resource lands have been identified and actions taken to conserve them, and its critical areas, including aquifers, are identified and protected, is it then possible and appropriate to determine where, on the remaining land, urban growth should be directed pursuant to RCW 36.70A.110.*[2]

RCW 36.70A.170(1) requires that all critical areas in all counties and cities must be designated where appropriate. The GMA permits no exemptions, exclusions, or limitations on applicability that would result in some critical areas not being designated. The requirement to designate may be met by designating or mapping known critical areas at the time the critical areas ordinance is adopted or by adopting a process to designate or map critical areas as information becomes available.

RCW 36.70A.060(2) requires all counties and cities in Washington to adopt development regulations to protect designated critical areas.[3] The Western Board has described RCW 36.70A.060(2) as imposing a *duty* on local governments to adopt development

regulations that protect critical areas; inherent in that duty is the requirement that the regulation contain appropriate and specific criteria and standards to ensure protection.[4]

All designated critical areas must be protected but not all critical areas must be protected in the same manner or to the same degree.[5] To "protect" critical areas means to maintain their values and functions, this requires no net loss of critical areas values and functions.[6] The required standard of protection should be to prevent adverse impacts or, at the very minimum, to mitigate adverse impacts.[7]

While local governments have discretion to adopt critical areas regulations that may result in local impacts upon some critical areas, or even the loss of some critical areas, there must be no net loss of the structure, value, and functions of the natural systems constituting the protected critical areas.[8] A county or city must provide a detailed and reasoned justification for any designated critical area not protected.[9] All such decisions and justifications must be based on a substantive consideration of the best available science.[10]

Development in critical areas is not absolutely prohibited under the GMA, so long as the structure, functions, and values of the critical areas are protected.[11]

The GMA does not categorically exempt pre-existing land uses from the requirement to protect critical areas. A city or county may need to regulate pre-existing uses in order to fulfill its statutory duty to "protect critical areas" under RCW 36.70A.060(2).[12] Any exemptions for pre-existing use must be limited and carefully crafted.[13]

Some critical areas, such as wetlands and fish and wildlife habitat conservation areas, may transcend the boundaries of individual parcels and jurisdictions, so that it is necessary to address the protection of their structure, function, and values on a larger scale (such as a watershed).[14]

2.3.2 Relationship of Critical Areas Regulations to Other Land Uses

Critical areas regulations are to overlay all other land uses, including designated natural resource lands and designated urban growth areas, and are to preclude land uses and developments that are incompatible with the protection of critical areas.[15] This overlay requirement makes sense in the overall scheme of the GMA, under which all lands are designated in one of three categories:

- Urban land (i.e., within a designated urban growth area)
- Natural resource land (i.e., designated as agricultural, forest, or mineral resource land)

- Rural land (which may include limited areas of more intense rural development and a variety of land uses)

These three designations have been called the "fundamental building blocks of land-use planning under the GMA;"[16] other land-use designations and restrictions overlay these three primary designations. As long as critical areas are protected, "other, non-critical portions of land can be developed as appropriate under the applicable land-use designation and zoning requirements."[17]

2.3.3 Including Best Available Science in Critical Areas Regulations

RCW 36.70A.172(1) requires all local governments to include the best available science when adopting development regulations to designate and protect critical areas. In addition, they "shall give special consideration to conservation or protection measures necessary to preserve or enhance anadromous fisheries." This language actually imposes three inter-related requirements:

- The requirement to include the best available science when designating and protecting critical areas
- The requirement to give special consideration to the preservation or enhancement of anadromous fisheries
- The requirement to adopt development regulations that protect the functions and values of critical areas

There are two reported appellate court decisions interpreting RCW 36.70A.172, focused primarily on what it means to *include* the best available science.[18] In the HEAL case, the Court did not attempt to explain what constitutes best available science, although it suggested in passing that the Board could not displace a local government's judgment as to which science in the record is the "best."[19] On the other hand, the Court strongly stated that a local government "cannot ignore the best available science in favor of the science it prefers simply because the latter supports the decision it wants to make."[20] This language suggests the Board in fact may review whether a local government has

[19] *Id.*, 96 Wn. App. at 530.

[20] *Id.*, 96 Wn. App. at 534.

identified and relied on the best available science and remand to the local government to achieve compliance with RCW 36.70A.172(1).

In the WEAN case (see footnote 18 on the previous page), the Central Board concluded that some of the stream buffers in Island County that were adopted to protect fish and wildlife habitat conservation areas were not supported by the scientific information in the record before the County. The Court of Appeals affirmed, rejecting the County's argument that the Board must defer to the local government's discretionary balancing of the best available science with other factors. The Court explained that RCW 36.70A.172(1) requires the best available science to be included in the record and considered substantively in the development of critical areas policies and regulations.[21] The Court briefly reviewed the science in the record and held that the Board's disapproval of the stream buffers was supported by sufficient evidence.

If a local government chooses to depart from best available science, then it is recommended that the jurisdiction follow the criteria provided in Chapter 365-195-915 WAC for demonstrating that the best available science has been "included" in the development of critical areas policies and regulations. The local government's record supporting adoption of those policies and regulations should include the following:

- The specific policies and regulations adopted to protect the functions and values of critical areas
- Copies of (or references to) the best available science used in the decision making
- The nonscientific information used as a basis for departing from science-based recommendations
- The rationale supporting the local government's reliance on the identified nonscientific information
- Actions taken to address potential risks to the functions and values of the critical areas the policies and regulations are intended to protect

Implicit in the rule is the presumption that the Growth Management Hearings Boards and the courts review both the local government's assessment of what constitutes the best available science and the substantive relationship between the best available science and the adopted critical areas regulations. Local governments must substantively consider the best available science when adopting development regulations to designate or protect critical areas. The adopted regulations must protect the functions and values of the critical areas. If the local government determines this protection can be assured using an approach different from that derived from the best available science, the local government must demonstrate on the record how the alternative approach will protect the functions and values of the critical areas.

[21] 76 Wn.2d at 1222-23, citing *Honesty in Environmental Analysis & Legislation (HEAL) v. Central Puget Sound Growth Management Hearings Board*, 96 Wn. App. 522, 532, 979 P.2d 864 (1999).

2.3.4 Protecting the Functions and Values of Critical Areas

Local governments must adopt development regulations that protect the functions and values of critical areas. This reference to functions and values has been interpreted to mean the functions and values of the resources of which a given critical area is a part. Accordingly, while a local government is not prohibited from allowing localized impacts on some critical areas, or even the loss of some critical areas, it may not allow a net loss of the functions and values of the resources including the impacted or lost critical areas. Moreover, any loss or adverse impact should be allowed only for good cause and evaluated using the best available science.

The Central Board has explained that RCW 36.70A.172(1), read together with RCW 36.70A.060 and RCW 36.70A.020(8), requires local governments to protect critical areas, maintain and enhance anadromous fisheries, and conserve fish and wildlife habitat.[22] RCW 36.70A.172(1) thus conveys a legislative intent to protect the functions and values of critical areas, recognizing that wetlands and fish and wildlife habitat conservation areas, in particular, are interrelated ecosystems important to the preservation and enhancement of anadromous fisheries:

> *[T]he Act's requirement to protect critical areas, particularly wetlands and fish and wildlife habitat conservation areas, means that the values and functions of such ecosystems must be maintained. While local governments have the discretion to adopt development regulations that may result in localized impacts upon, or even the loss of, some critical areas, such flexibility must be wielded sparingly and carefully for good cause, and in no case result in a net loss of the value and functions of such ecosystems within a watershed or other functional catchment area*.[23]

Chapter 3
Key Conclusions from Volume 1

3.1 Introduction

This chapter briefly summarizes the information and conclusions presented in Volume 1 of this two-volume document. The first section highlights the major conclusions from the scientific literature that relate to protecting and managing wetlands. The subsequent sections summarize the findings of Chapters 2 through 7 of Volume 1.

Please note that this is intended to be a brief overview of Volume 1. More detailed lists of key points and discussions of conclusions are provided at the end of major sections in each chapter of Volume 1.

3.2 Major Conclusions About Our Current Efforts to Protect Wetlands

In spite of wetland regulatory programs at federal, state, and local levels, the data show that impacts to wetlands continue. The existing scientific information points to the fact that we have not achieved the federal and the state of Washington goal of "no net loss of wetland functions or area." From 1986 to 1997, the estimated annual loss of wetlands nationwide continued to be about 58,500 acres per year. On a positive note, this was about a quarter of the rate of previous losses (National Research Council 2001). Such losses of wetlands have also been documented for the Pacific Northwest (see Chapter 7 in Volume 1).

The review of the information on how we manage wetlands points to several reasons why losses continue. These include:

- Case-by-case permitting under current regulations does not meet the goal of "no net loss" (National Research Council 2001). The majority of decisions concerning wetlands in Washington State and the nation are based on case-by-case actions related to specific projects, without any opportunity to consider the broader landscape, the environmental factors that control wetland functions, or consequences. This pattern is a result of the current structure of programs at local, state, and federal regulatory agencies. The results of the research on case-by-case permitting processes are clear: There are consistent wetland losses regionally and statewide. These impacts are often the result of cumulative and synergistic impacts across the landscape.

- The functions performed by wetlands can be affected by actions taken in other parts of the watershed (see Chapter 2 in Volume 1).

- Decisions made without an understanding of how a wetland is affected by and can affect its watershed often result in actions that do not adequately protect functions of wetlands. Since the case-by-case approach has not worked to ensure that there is "no net loss" of wetland area and functions for over 20 years, it can be assumed that wetlands and their functions will be adequately protected to meet this goal only if protection and management occur at a larger geographic scale. The National Research Council (2001) concludes that "a watershed approach would improve permit decision-making."

3.3 Wetlands in Washington and How They Function (Chapter 2 of Volume 1)

3.3.1 Types of Wetland Functions and How They Are Controlled

Chapter 2 of Volume 1 discusses the functions of wetlands, which are things that wetlands "do." Wetland functions are generally grouped into three broad categories:

- Biogeochemical functions, which are related to trapping and transforming chemicals and include functions that improve water quality in the watershed
- Hydrologic functions, which are related to maintaining the water regime in a watershed and include such functions as reducing flooding
- Food web and habitat functions

The functions that wetlands perform are controlled by environmental factors that occur in the broader landscape as well as within the wetland. The primary factors that control wetland functions are climate, geomorphology, the source of water, and the movement of water. These factors affect wetland functions directly or through a series of secondary factors including nutrients, salts, toxic contaminants, soils, temperature, and the connections between different ecosystems.

The most important environmental factors that control wetland functions at an individual site may occur outside the boundary of the wetland. For example, riverine wetlands are affected to a great degree by processes operating at the scale of the entire watershed of the river. In contrast, depressional wetlands often are subject to processes that occur primarily within the basin that contributes surface or groundwater to the wetland. Thus, the environmental factors that control the structure and functions of a wetland occur at both the landscape scale (in the watershed where the wetland is located and beyond) as well as at the site scale (within and near the wetland).

Information about the factors that control functions at the landscape scale is still evolving. Ongoing research is continually strengthening our understanding of these factors.

An understanding of wetland functions for the purposes of protecting and managing them will require knowledge of how the major controls of functions change or are affected by humans at different geographic scales. We need to understand how climate, topography, and the movement of water, nutrients, sediment, etc. are affected by human activities in the larger landscape as well as within and in the immediate vicinity of the wetland. Environmental disturbances caused by human activities and their affects on the functions of wetlands are summarized in Sections 3.3 and 3.4 below.

3.3.2 Classification of Wetlands in Washington as a Key to Understanding Their Functions

The diverse areas of Washington State support many kinds of wetlands that vary in functions. For example, vernal pools on the scablands differ greatly from the floodplain marshes along the Snoqualmie River, and wetlands that formed in the potholes created by glaciers have different functions from those found along the shores of salt lakes in the Grand Coulee.

Scientists have divided wetlands in Washington into different groups based on their functions (see Table 3-1). The environmental factors of geomorphology, the source of water, and the movement of water are the basic characteristics used to divide wetlands into these groups.

Table 3-1. Subclasses and families of wetlands in different regions of Washington State. (Hruby et al. 1999, 2000)

Class	Subclasses and Families by Region			
	Lowlands of Western WA	**Lowlands of Eastern WA**	**Columbia Basin**	**Montane (East and West)**
Riverine	Impounding Flow-through	ND	ND	ND
Depressional	Outflow Closed	ND	Alkali Freshwater Long-duration Short-duration	ND
Slope	ND	ND	ND	ND
Flats	ND	Probably does not occur in the region.	Probably does not occur in the region.	ND
Lacustrine (lake) Fringe	ND	ND	ND	ND
Tidal Fringe	Salt Water Fresh Water	Does not occur in the region.	Does not occur in the region.	Does not occur in the region.
ND = Subclasses in the region have not yet been defined.				

3.4 Environmental Disturbances Caused by Human Activities and Uses of the Land (Chapter 3 of Volume 1)

Chapter 3 of Volume 1 discusses the major types of environmental disturbances created by human activities and uses of the land and water. These disturbances change the environmental factors that in turn control wetland functions. Chapter 3 of Volume 1 addresses the disturbances created by four major types of land uses in Washington State: agriculture, urbanization, forest practices, and mining.

Several types of disturbances have been documented to change the factors that control wetland functions. These disturbances include:

- Changing the physical structure within a wetland (e.g., filling, removing vegetation, tilling soils, compacting soils)
- Changing the amount and velocity of water (either increasing or decreasing)
- Changing the fluctuation of water levels (volume, frequency, amplitude, direction of flow)
- Changing the amount of sediment (increasing or decreasing the amount)
- Increasing the amount of nutrients
- Increasing the amount of toxic contaminants
- Changing the temperature
- Changing the acidity (acidification)
- Increasing the concentration of salt (salinization)
- Fragmentation (decreasing area of habitat and its spatial configuration)
- Other disturbances that are not as well documented including, alteration of soils, construction of roads, noise, recreational access, invasion of exotic species, and access by domestic pets

As with performance of functions, a general conclusion that can be made from the scientific literature is that disturbances can also occur at several geographic scales. Much of the early research focused on disturbances at a single site or wetland. More recent research has documented the significance of disturbances that occur at the much larger scale of the landscape.

The effects of different human land uses on the flow and fluctuations of water are well documented. Changes in land uses and vegetation communities alter the patterns of surface and shallow groundwater movement across a landscape. Flows of water can be

reduced or increased by different land uses, as can the volume, frequency, and amplitude of water levels downgradient of the disturbance. Removal of vegetation and/or compaction of native soils through agricultural practices, creation of lawns or grazed pastures, or creation of impervious surfaces through urbanization all have the same relative consequence: increased volumes of water and rates of flow after a given storm event. As with urbanization, agriculture can influence the water regime of wetlands, leading to loss of wetlands in some areas and creation or maintenance of wetlands in other areas where wetlands did not originally exist, such as areas influenced by irrigation.

Human activities also increase sediment and other pollutants in runoff. Pollutants often adhere to sediment particles that enter wetlands. In agricultural areas, pesticides and fertilizers can contribute to contamination of surface waters. In urban areas, stormwater runoff frequently contains sediment, organic matter, phosphorus, metals, and other pollutants. Mining increases the acidity of surface waters as well as adding toxic heavy metals. Logging increases sediments and can also change the amount of water and its fluctuations.

Fragmentation of habitats is also of increasing concern in the literature. As connections between wetlands and other habitats are broken and more wetlands across the landscape are converted to other uses, the remaining habitat becomes more isolated. This potentially puts wildlife populations at risk.

A key finding is that different land uses may cause the same change in the controls of wetland functions. For example, changing the input of sediment can affect wetland functions (as discussed in Section 3.4 below). Urban land uses, agricultural practices, and forest practices have all been shown to increase sediments in a watershed. From the wetland's "point of view," the source of the sediment is irrelevant—the impact of excess sediments on wetland functions is similar, regardless of the source of the sediments.

The disturbances created by some types of land use are summarized in Table 3-2. The table is organized by the type of land use and the scale at which the disturbance occurs. This table represents a synthesis of the severity of impacts as compiled by the authors of Volume 1 based on the information in the literature.

Table 3-2. Summary of types of environmental disturbances created by some types of land use.

Disturbance	Scale of Disturbance	Agriculture	Urbanization	Mining
Changing the physical structure within wetlands (filling, vegetation removal, tilling of soils, compaction of soils)	Site scale	xx	xx	h
Changing the amounts of water	Landscape scale	xx	xx	?
	Site scale	xx	xx	h
Changing fluctuations of water levels (frequency, amplitude, direction of flows)	Landscape scale	xx	xx	?
	Site scale	xx	xx	h
Changing the amounts of sediment	Landscape scale	xx	xx	h
	Site scale	xx	xx	h
Increasing the amount of nutrients	Landscape scale	xx	xx	nm
	Site scale	xx	xx	nm
Increasing the amount of toxic contaminants	Landscape scale	xx	xx	x
	Site scale	xx	xx	xx
Changing the acidity	Landscape scale	nm	nm	x
	Site scale	nm	nm	xx
Increasing the concentrations of salt	Landscape scale	x	nm	nm
	Site scale	x	nm	nm
Fragmentation	Landscape scale	xx	xx	h
Other disturbances	Site scale	xx	xx	h

Key to symbols used in table:

(xx) land use creates a major disturbance of environmental factors that affects large areas in the state

(x) land use creates a disturbance

(nm) studies on impacts of this land use do not mention this disturbance

(h) literature is lacking but disturbances can be hypothesized based on authors' experiences

(?) information lacking

3.5 Negative Impacts of Human Disturbances on the Functions of Wetlands (Chapter 4 of Volume 1)

As described above, Chapter 3 of Volume 1 discusses how human land uses cause disturbances in the environmental factors that control wetland functions. Chapter 4 takes the discussion a step further by explaining how a change in these environmental factors can actually result in a change in wetland functions.

The literature findings are displayed in a summary format in Table 3-3. This table summarizes the effects on wetland functions of each type of human disturbance listed in Table 3-2 (e.g., change in physical structure, change in the amount of water, change in the amount of sediment, etc.).

By combining the information in Tables 3-2 and 3-3, it is possible to associate changes in functions of wetlands with general types of human land use, as shown in Table 3-4.

For example, Table 3-2 shows that urbanization creates significant disturbances that change the amount of water, fluctuations of water levels, input of sediments, nutrients, and contaminants to wetlands. Table 3-3 shows that disturbances to water flows, fluctuations of water levels, and input of sediments, nutrients, and contaminants have a significant impact on the wetland functions of providing habitat for plants, invertebrates and reptiles/amphibians. Table 3-4 synthesizes the information from the previous two tables to show that urbanization impacts the habitat for plants, invertebrates, reptiles, and amphibians in wetlands. These tables, therefore, summarize how human land uses create various disturbances in the environment, and those disturbances in turn affect the factors that control wetland functions, ultimately leading to changes in those functions.

Table 3-3. Synthesis of the information reported in the literature on the negative impacts of different human disturbances on wetland functions.

Disturbance Type	Functions							
	Hydrologic	Water Quality	Plants	Habitat for Invertebrates	Habitat for Amphibians and Reptiles	Habitat for Fish	Habitat for Birds	Habitat for Mammals
Changing the physical structure within a wetland	+	+	++	++	+	+	++	+
Changing the amount of water	+	+	++	++	++	+	+	?
Changing fluctuations of water levels	?	?	++	+	++	+	?	?
Changing amounts of sediment	+	?	++	++	?	?	?	?
Increasing amounts of nutrients	+	+	++	++	++	+	+	+
Increasing amounts of toxic contaminants	?	+	++	++	++	++	++	?
Changing acidity	0	+	+	++	++	+	+	+
Increasing concentrations of salt	0	?	++	++	?	?	+	?
Fragmentation	0	?	?	?	++	?	++	+
Other disturbances	?	?	++	+	++	++	++	++

Note: A disturbance can decrease or increase a function depending on the intensity of the disturbance (e.g., small amounts of nutrients can increase invertebrate richness and abundance, but too much will cause eutrophication and a negative impact).

Key to symbols used in table:

++	Major negative impacts on specific functions have been documented
+	Some data suggest impacts, or impacts could be hypothesized
0	Data indicate that impacts are minimal
?	Information is lacking and/or may vary by species

Table 3-4. Synthesis of the negative impacts of some land uses on wetland functions.

Land Use	Functions							
	Hydrologic	Water Quality Improvement	Plants	Habitat for Invertebrates	Habitat for Reptiles and Amphibians	Habitat for Fish	Habitat for Birds	Habitat for Mammals
Agriculture	+	+	++	++	++	++	++	+?
Urbanization	+	+	++	++	++	++	++	+?
Mining	?	?	+	++	++	+	+	+?

Key to symbols used in table:

++ Major negative impacts on specific functions have been documented
+ Some data suggest impacts or impacts could be hypothesized
? Information is lacking
+? Some impacts have been documented but more information is needed

3.6 The Science and Effectiveness of Wetland Management Tools (Chapter 5 of Volume 1)

3.6.1 How Wetlands Are Defined

Wetlands are defined using well established language that is generally consistent between federal and Washington State laws. In some jurisdictions, all lands that meet the definition of wetland are regulated. However, it is not unusual for a jurisdiction to differentiate within its regulations between *wetlands* (i.e., biological wetlands) and *regulated wetlands* (i.e., wetlands that they intend to regulate). The definition of what constitutes a regulated wetland may vary from jurisdiction to jurisdiction.

Delineation of wetland boundaries is conducted according to either the federal or state delineation manual. These manuals are consistent and, when applied correctly, will result in the same wetland boundary. In the State of Washington, however, local jurisdictions are required by state law to use the state manual (RCW 36.70A.175, Chapter 173.22.080 WAC).

As discussed in Chapter 5 of Volume 1, certain wetland types are sometimes excluded from regulation. These can include small wetlands, isolated wetlands, and wetlands that are designated as Prior Converted Croplands. The scientific literature makes clear that small wetlands and isolated wetlands provide important functions and does not provide any rationale for excluding these wetlands from regulation. Little scientific information is available on Prior Converted Croplands that are wetlands, but there is no evidence to suggest that they are unimportant in providing wetland functions.

Wetland rating systems are a useful tool for grouping wetlands based on their needs for protection. In Washington, a wetland rating system for both eastern and western Washington (Hruby 2004a, 2004b) has been developed, which places wetlands in categories based on their rarity, sensitivity, our inability to replace them, and their functions. Many local governments in Washington have modified these state rating systems for use in their own jurisdictions.

3.6.2 Wetland Buffers

Wetland buffers are one management tool for protecting wetland functions. The findings in the literature on buffers and their effectiveness are related to the type of wetland function, what activities are being buffered, and the characteristics of the wetland and the buffer itself.

The literature confirms that for improving water quality (e.g., sediment removal and nutrient uptake) there is a non-linear relationship between the width of the buffer and increased effectiveness in water quality improvement. Sediment removal and nutrient uptake are provided at the greatest rates within the immediate outer portions of a buffer (nearest the source of sediment/nutrient), with increasingly larger widths of buffers required to obtain measurable increases in those functions beyond this initial removal. Additionally, the long-term effectiveness of buffers in providing this function is not well documented in the literature and represents a need for future research.

To protect wildlife that depends on wetlands, the literature has documented the need for significantly larger buffers than those that are adequate to provide sediment removal and nutrient uptake. Research confirms that many wildlife species depend upon wetlands for only portions of their life cycles and they require upland habitats adjacent to the wetland to meet all their life needs. Some species use upland habitats that are far removed from the wetland. The literature documents that, without access to appropriate upland habitat and the opportunity to move safely between habitats across a landscape, it is not possible to maintain viable populations of many species.

In the long term, human actions can reduce the effectiveness of buffers through removal of buffer vegetation, soil compaction, sediment loading, and dumping of garbage.

Authors who synthesized the literature on the effectiveness of buffer widths suggest buffers between 25 and 75 feet for wetlands with minimal wildlife habitat functions and adjacent low-intensity land uses; 50 to 150 feet for wetlands with moderate habitat functions or adjacent high-intensity land uses; and 150 to 300 feet for wetlands with high habitat functions. Effective buffer widths for protecting water quality ranged from 25 to 50 feet for 60% removal of pollutants, to 150 to 200 feet for 80% removal of pollutants.

3.7 The Science and Effectiveness of Wetland Mitigation (Chapter 6 of Volume 1)

As discussed in Chapter 6 of Volume 1, according to the rules implementing the Washington State Environmental Policy Act (Chapter 197.11 WAC), mitigation involves the following steps that are performed sequentially (WAC 197.11.768):

1. *Avoiding the impact altogether by not taking a certain action or parts of an action;*

2. *Minimizing impacts by limiting the degree or magnitude of the action and its implementation by using appropriate technology or by taking affirmative steps to avoid or reduce impacts;*

3. *Rectifying the impact by repairing, rehabilitating, or restoring the affected environment;*

4. *Reducing or eliminating the impact over time by preservation and maintenance operations during the life of the action;*

5. *Compensating for the impact by replacing, enhancing, or providing substitute resources or environments; and/or*

6. *Monitoring the impact and taking appropriate corrective measures.*

The term *compensatory mitigation* refers to the compensation stage of the mitigation sequence (number 5 in the list of steps above). For wetlands, it typically involves producing new wetland area, functions, or both as compensation for wetland area, function, or both that have been or will be lost due to a permitted activity. Compensatory wetland mitigation generally entails performing one or more of the following types of compensation:

- **Restoring** wetland conditions (and functions) to an area
- **Creating** new wetland area and functions
- **Enhancing** functions at an existing wetland
- **Preserving** an existing high-quality wetland to protect it from future development

Chapter 6 of Volume 1 synthesizes the literature on compensatory mitigation from the last 15 years. The majority of projects that provide compensatory mitigation described in the literature have been neither fully successful nor complete failures. One challenge in synthesizing this information was the range of meanings for and the implications of the very terms success and failure.

3.7.1 Compliance of Projects with Permit Requirements (Volume 1 Section 6.4)

While most of the mitigation projects documented in the literature were implemented, compliance of the projects with permit requirements was generally low. This was a result of inadequate acreage of wetland, failure to achieve performance standards, and a lack of monitoring and maintenance. The few studies that examined the effect of regulatory follow-up suggested that it had a positive influence on the level of compliance and success for compensatory wetland mitigation projects.

3.7.2 Ecological Effectiveness of Different Types of Compensation (Volume 1 Section 6.5)

There is a general lack of information about the relative ecological effectiveness of the various types of compensation (e.g., restoration, creation, enhancement, etc.). Creation is generally the most frequently used type of compensation, but studies of its effectiveness produced mixed results.

Enhancement of wetlands is also frequently used, but few studies have examined its effectiveness. Limited studies from Washington indicated a low level of success among enhanced wetlands, primarily due to a minimal gain in functions in the timeframe between construction of the mitigation project and the evaluation of gain in functions. It may simply take longer for a gain in functions to appear (15 to 20 years rather than 5 to 10 years).

Restoring wetlands was noted as a high priority in the literature, but this type of compensation is not frequently used. This could be because restoration is often not an option on a project-by-project basis when costs and local regulations defer to on-site mitigation options. Restoration appears to be a more frequent choice in non-regulatory situations.

Preservation and the use of a mixture of compensation types appear to be used occasionally based on the literature review, and studies provided limited information on the effectiveness of these types of compensation. Two studies from Washington indicated that mixed compensation projects had a higher level of compliance than creation or enhancement, and all mixed projects were moderately successful.

3.7.3 Replacement Ratios (Volume 1 Section 6.6)

Replacement ratios are a tool used to account for the risk of mitigation failure and the temporal loss of functions. Required replacement ratios vary from one jurisdiction to another, based on the type of compensation proposed and project-specific circumstances.

The review of the literature indicated that the wetland functions and acreage achieved by using replacement ratios were less than what was required. In some cases the result was less than 1:1 replacement of acreage and a net loss of wetland acreage and function on the landscape.

3.7.4 Functions and Characteristics of Mitigation Wetlands (Volume 1 Section 6.8)

The functions performed and the structural characteristics that developed in created and restored wetlands usually differed from those in reference wetlands discussed in the literature. The one exception was the group of functions that improve water quality; these appeared to be performed in a similar capacity in mitigation wetlands as in reference wetlands. (Studies reviewed for Volume 1 did not compare the functions provided by wetlands that had been developed as compensation against the functions provided by the wetlands that were lost. Instead, reference wetlands were used as the basis for comparison with mitigation wetlands.)

For the most part, reference wetlands were found to provide habitat for a greater diversity or abundance of wildlife than created or restored wetlands. Birds were an exception since half of the studies found no difference between created/restored sites and reference wetlands, particularly for ducks.

Created and restored wetlands were also found to exhibit different vegetation characteristics and plant communities than reference wetlands. The effect of wetland age on the vegetation of created and restored wetlands was noted in various studies.

3.7.5 Types of Wetlands Produced through Compensation Projects (Volume 1 Section 6.9)

The review of the literature indicates that compensatory mitigation is producing more acreage of open water wetlands than has been lost. The ability of compensatory mitigation projects to produce wetlands of other Cowardin classes (e.g., emergent, scrub-shrub, forested) varies.

Compensatory mitigation is also producing wetlands with significantly different hydrogeomorphic (HGM) classes than were present in the reference wetlands near that location. (The HGM classification is based on the position of the wetland in the landscape, the wetland's water source, and the flow and fluctuation of the water once in the wetland.) This has resulted in mitigation wetlands that have more inundation for a longer period than in reference wetlands, as well as HGM classes of wetlands that are atypical for the landscapes in which they are being created.

Some unique types of wetlands, such as bogs, fens, and mature forested wetlands, may not be reproducible, especially not within current regulatory timeframes. Other wetland types, such as vernal pools, may be reproducible given the right conditions.

3.7.6 Suggestions for Improving Compensatory Mitigation (Volume 1 Section 6.10)

The literature provides numerous suggestions on virtually every aspect of the compensatory mitigation process. Key suggestions include:

- Improving regulatory guidance on a variety of topics, such as measurable, meaningful, and enforceable performance standards for compensatory mitigation
- Finding better sites that provide increased benefits due to their location within a watershed
- Monitoring compensatory mitigation wetlands more effectively
- Maintaining compensatory mitigation sites
- Increasing the regulatory follow-up of compensation projects

The review of the literature indicates that improvements have been made in compensatory mitigation over the past two decades, particularly in terms of what is required. Based on the research reviewed, the overall success and permit compliance have not noticeably improved. Most studies indicate that created and restored wetlands do not provide the same characteristics or level of functions as reference wetlands (water quality functions may be the exception). Though older created and restored wetlands generally exhibit characteristics of the vegetation that lead to improved habitat for wildlife, the soils and the hydroperiods may remain so modified that they will not replicate reference systems in the foreseeable future. Since the effectiveness of compensatory mitigation remains highly variable, it is important to understand the cumulative effects of the continuing loss of wetland acreage and functions (summarized in the next section).

3.8 Cumulative Impacts to Wetlands and the Need for a New Approach (Chapter 7 of Volume 1)

The literature reviewed for Volume 1 indicates that project-by-project decisions cannot, by their very site-specific nature, adequately address the complexities of wetland systems as they function in a landscape context. The majority of wetland management decisions in Washington State are related to individual projects, without an opportunity to consider the environmental factors that control functions or cumulative impacts.

As discussed in Chapter 7 of Volume 1, the causes of cumulative impacts are not limited to the policies or regulations of a single agency but can also result from multiple agencies making land-use decisions in isolation. Also, cumulative effects are difficult to assess because of the large spatial and temporal scales involved, the wide variety of processes and interactions, and the lag times that often separate a land use activity from resulting effects.

While the literature did not focus on the reasons for the lack of landscape-scale wetland management in Washington, some impediments can be assumed:

- The costs of analysis, inventories, assessments, and rankings
- The costs of implementing a landscape-scale program relative to existing project-driven programs that are often funded by applicant fees
- Inconsistent mandates driving the agendas and priorities of regulatory agencies
- Lack of examples of successful tools for interagency collaboration and implementation
- Lack of awareness and understanding of the ecological consequences of existing regulatory programs by the public and the staff of implementing agencies
- Lack of support for local jurisdictions to tackle the process of identifying and prioritizing aquatic resources for long-term protection and/or potential alteration

The literature recommends a broader approach for the management and restoration of aquatic resources including wetlands. Researchers recognize the need for an analysis of the broader landscape and the environmental factors that control functions and cumulative effects (i.e., the historic, ongoing, and future impacts on an ecosystem).

For this reason, the guidance provided in Volume 2 stresses the importance of starting with an understanding of the landscape as well as wetland functions at the site scale. This understanding of the landscape can then be incorporated into more effective planning, regulatory, and non-regulatory tools.

Chapter 4

Framework for Protecting and Managing Wetlands Using Best Available Science

4.1 Introduction

This chapter outlines a four-step framework for developing and implementing approaches to wetland protection and management by local governments. This chapter introduces the four steps of this framework and the feedback loop called "adaptive management." Following chapters describe each step in more detail. Examples and additional information are provided in the appendices.

The framework is an adaptation of one developed for the *Statewide Strategy to Recover Salmon* (Washington State Joint Natural Resources Cabinet 1999). The framework incorporates the findings of the synthesis of the science from Volume 1, such as using landscape analysis to guide the decision-making process when developing plans, policies, codes, ordinances, and non-regulatory approaches to protecting and managing wetlands. One goal of the framework, as presented here, is to help local governments integrate all of their activities relating to wetlands so they can work together. The integration of analyses, planning, regulations, and non-regulatory activities by a local government can be considered its "wetland protection program."

The review of the literature in Chapter 2 of Volume 1 emphasizes that wetlands are an integral part of the landscape. Therefore, to protect and manage wetlands and reduce cumulative impacts, local governments need to understand how changes in land use that result from human activities at a landscape scale can affect wetlands at the smaller, site scale. Once such an understanding is developed, it is possible to plan for, and minimize, the impacts of human activities at all geographic scales, and thereby effectively protect wetlands and their functions.

Analyzing the landscape that influences wetlands is a relatively new idea. Planners and managers of natural resources face a challenge in incorporating landscape information into the planning and protection process. Three common questions posed by planners and managers are:

- What are landscape processes and what do we know about them and their interaction with wetlands?
- What tools can be used to most effectively incorporate a landscape perspective into wetland management?
- How do we organize planning and protection activities to incorporate information about the landscape as well as protecting individual wetlands?

The first question is answered in Chapter 5, which describes what is meant by a landscape analysis. The last two questions are answered in the guidance provided in subsequent chapters and appendices in this document. Collectively, the framework for a program to protect wetlands described below can help minimize cumulative impacts.

Key terms used in this document to describe processes and functions

Landscape processes - Environmental factors that occur at larger geographic scales, such as basins, sub-basins, and watersheds. Processes are dynamic and usually represent the movement of a basic environmental characteristic, such as water, sediment, nutrients and chemicals, energy, or animals and plants. The interaction of landscape processes with the physical environment creates specific geographic locations where groundwater is recharged, flood waters are stored, stream water is oxygenated, and pollutants are removed, and wetlands are created.

Wetland functions - The physical, biological, chemical, and geologic interactions among different components of the environment that occur within a wetland. There are many valuable functions that wetlands perform but these can be grouped into three categories: functions that improve water quality, functions that change the water regime in a watershed such as flood storage, and functions that provide habitat for plants and animals.

4.2 Four-Step Framework for Protecting and Managing Wetlands

The framework for protecting and managing wetlands is designed to provide a number of opportunities to incorporate landscape information into decision-making at the planning stages as well as into decisions regarding individual wetlands. The four steps of the framework include:

1. Analyzing landscape processes that influence wetland resources (called "landscape analysis"), as well as processes that occur at the scale of the site itself

2. Prescribing solutions for protecting and managing wetlands based on information from Step 1 (such as developing policies, plans, codes, ordinances, and non-regulatory approaches, etc.)

3. Taking actions to implement the solutions (such as applying regulations at individual wetlands, restoring wetlands, and providing non-regulatory incentives)

4. Monitoring the results of the actions taken and the effectiveness of the solutions (such as tracking acreage and functions of wetlands lost and gained and determining whether plans and programs are being implemented); this information will help determine if cumulative impacts are occurring

The four-step framework should be iterative and ongoing. If the data collected through monitoring in the fourth step indicates that wetlands are not being adequately protected and cumulative impacts are occurring, the management actions need to be revised accordingly. Evaluation of the monitoring data initiates a feedback loop called adaptive management.

Figure 4-1 conceptually illustrates the four-step framework that can be used by local governments to develop and implement effective approaches to protecting wetlands and other critical areas. The first two steps—analyzing the landscape and its wetlands and prescribing solutions—can be considered long-term planning, and the second two—taking actions and monitoring results—as implementation. As mentioned previously, an additional component is the feedback loop, called adaptive management. This is the process of assessing what has or has not been effective and making modifications based on these insights.

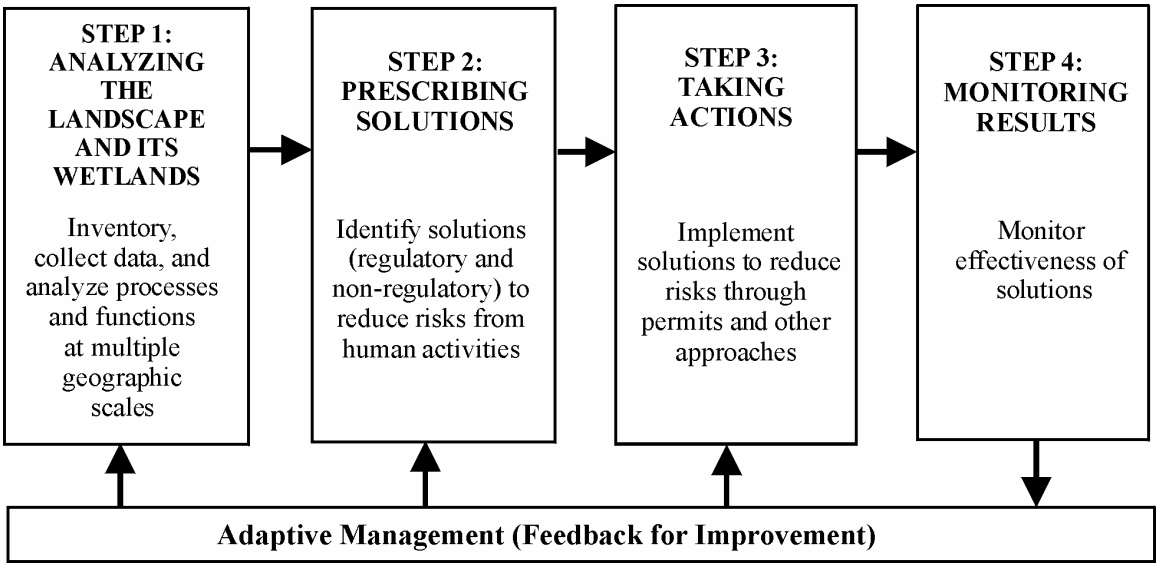

Figure 4-1. A suggested framework for local governments to use in protecting and managing wetlands. These four steps serve as the framework for discussions in this volume and are reproduced at the beginning of each chapter.

4.2.1 Incorporating Different Geographic Scales in the Four-Step Framework

The synthesis of the science presented in Volume 1, and the ecological principles listed in Chapter 1 of this volume, indicate the need for analyzing, planning, and managing at a landscape scale as well as at the scale of individual sites. Therefore, the words used to describe different scales must be clarified to provide a "common language."

Local governments can protect and manage wetlands at different geographic scales. Three geographic scales are discussed in this document. These are the *contributing landscape***,** the *management area*, and the *site*, described in the box below**.** Figure 4-2 provides an example of these three geographic scales.

Geographic scales discussed in this document

The ***contributing landscape*** is the geographic area within which the landscape processes that influence the functions or structure of wetlands located in a *management area* (defined below) occur. A contributing landscape may span jurisdictional boundaries and even span several watersheds (see Figure 4-2). Given that the contributing landscape may cross jurisdictional boundaries, efforts to protect the wetlands need to be coordinated and integrated with programs of other local governments. Because most ecosystems are linked across the landscape, it is important that measures to protect wetlands are coordinated with measures for protecting other resources including riparian areas, floodplains, estuaries, shorelines, and fish and wildlife habitat.

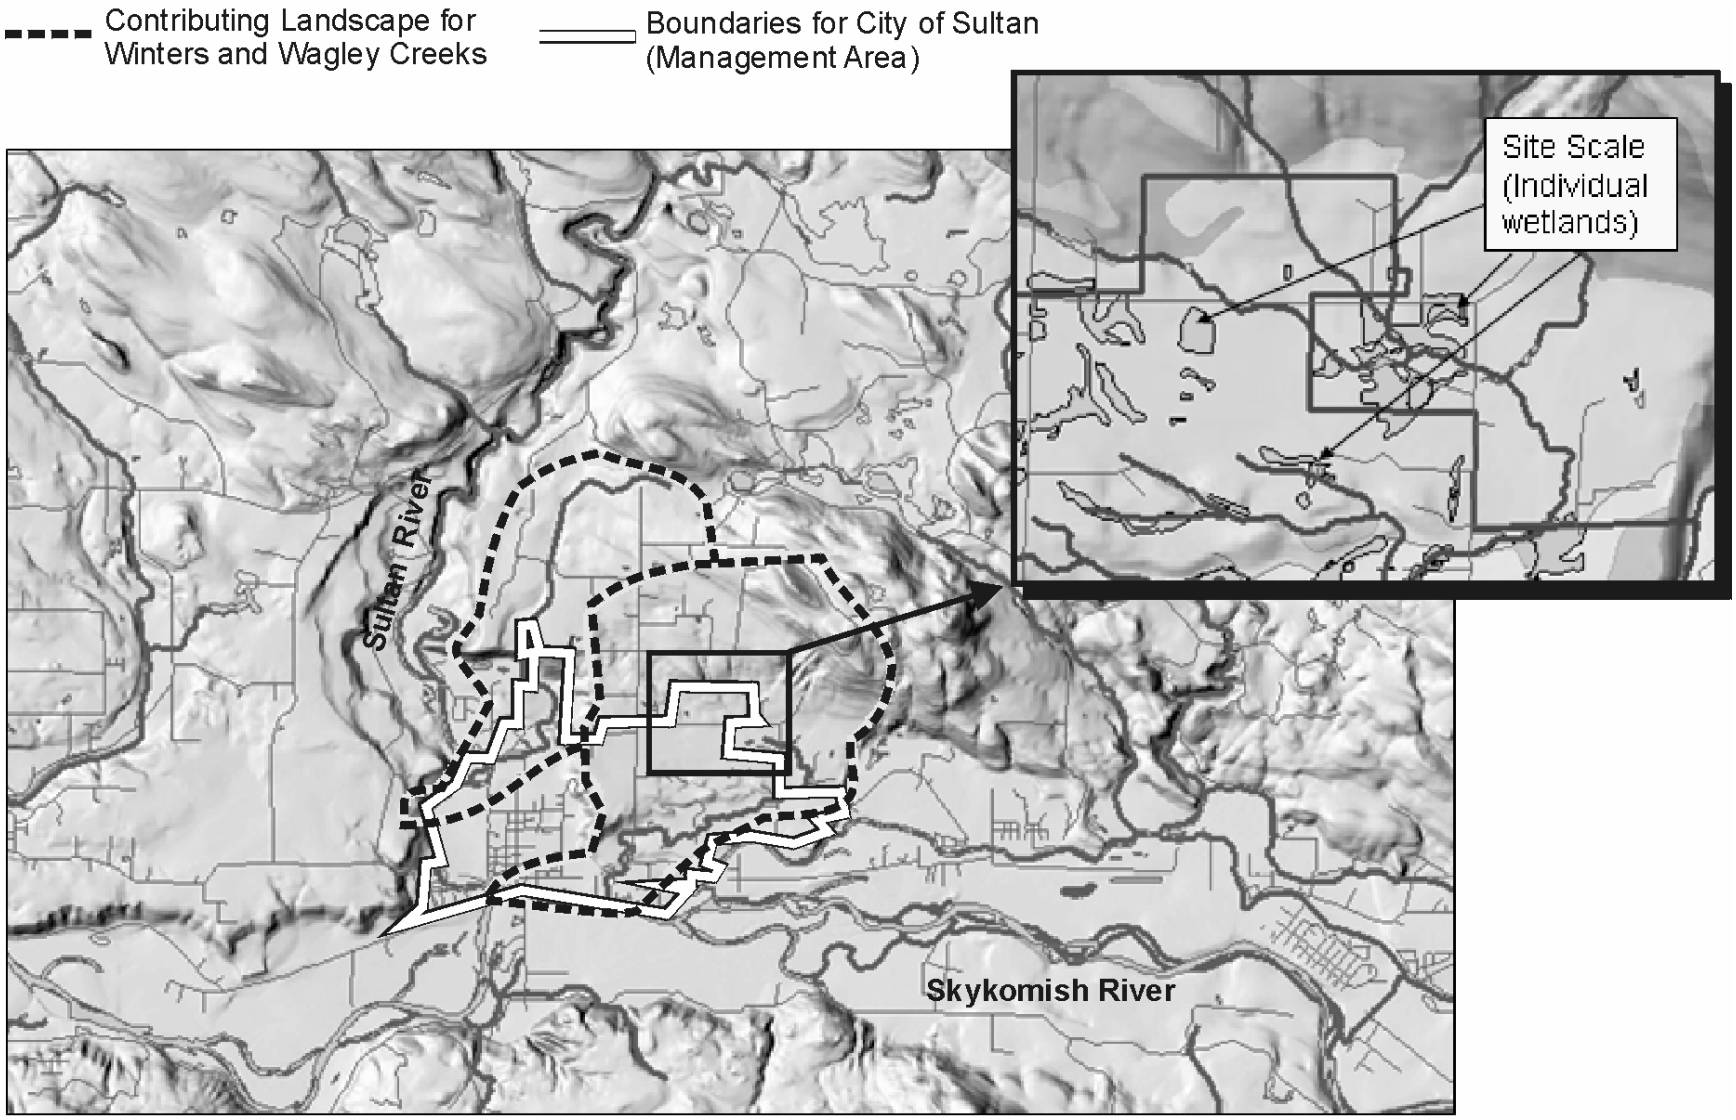
The ***management area*** is the geographic area for which plans and regulations are being developed by a local government. The management area is usually a subset of the contributing landscape because it may be based on political boundaries (e.g., a jurisdiction such as a city), or it may be defined geographically to include a specific Water Resource Inventory Area (WRIA), basin, or sub-basin in a county.

The ***site*** is the area encompassed within the boundary of a single wetland. It, too, may span private property lines or jurisdictional boundaries.

In Figure 4-3, each of the four steps of the framework described earlier is divided into a series of actions that would be undertaken at each of these three geographic scales.

Steps 1 through 4 of the framework are described in detail following the figures.

Figure 4-2. An example of contributing landscape, management area, and site scales.



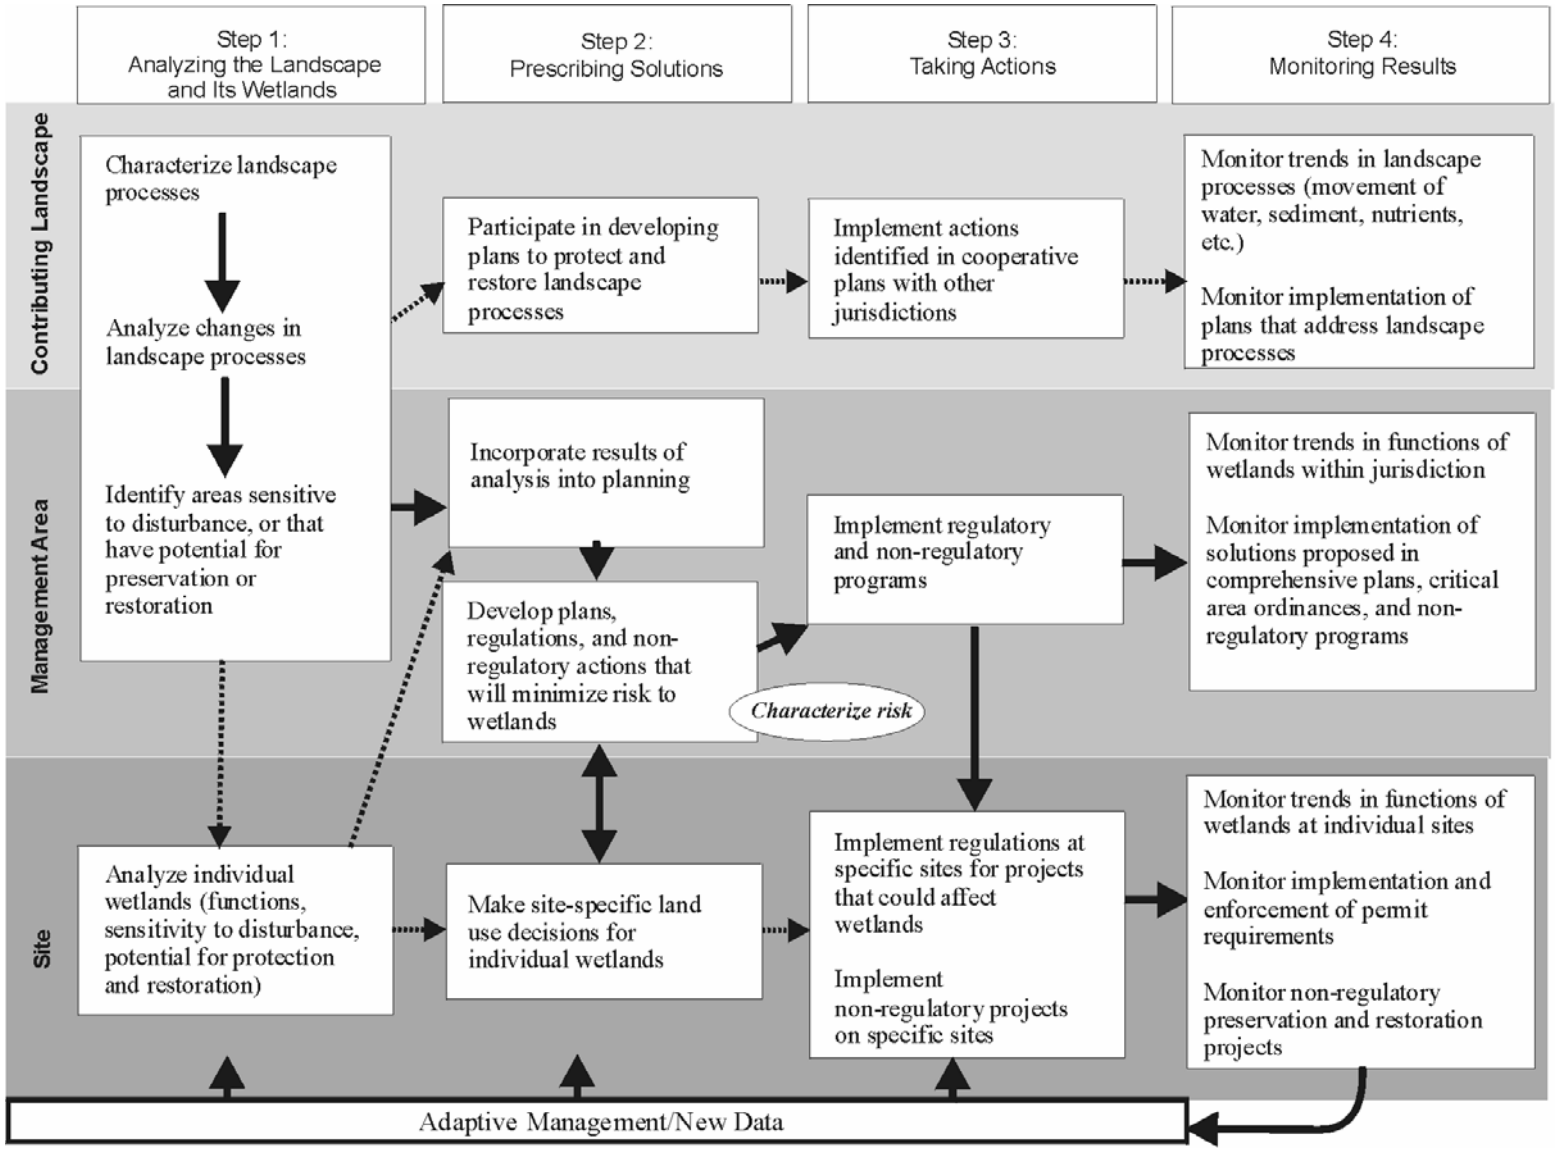


Figure 4-3. Four-step framework incorporating the three geographic scales. Solid arrows represent the process that should be undertaken in developing comprehensive plans and critical areas ordinances. Dashed arrows show additional pathways that can be followed to enhance a protection and management program for wetlands.

4.2.2 Step 1: Analyzing the Landscape and Its Wetlands (Landscape Analysis)

Step 1 involves a *landscape analysis*, which is needed to understand landscape processes and their influence on wetlands. A landscape analysis provides important information that forms the basis of a program to protect wetlands. For example, information from a landscape analysis is crucial in developing comprehensive plans (see Chapter 7) or for planning under an Alternative Futures approach (see Chapter 6). The analysis is applicable to all types of planning done at the scale of the watershed, sub-basin, contributing basin, or site. For example, a landscape analysis can be used to interpret an analysis of the functions of an individual wetland when a change in land use is being considered.

As will be discussed in Chapter 5, a landscape analysis is more complex than what is typically required for a wetland inventory, though the two share some similarities. When doing a landscape analysis, it is recommended that annotated maps be produced that identify areas of critical concern for managing wetlands and their contributing landscape. A series of annotated maps can summarize complex geographic information and provide a scientific basis for establishing land-use designations and in making other decisions about land use. The information can be used in evaluating the relative impacts for a range of alternative scenarios of future development, such as Alternative Futures, that are created in Step 2.

The paragraphs below briefly describe Step 1 at the various geographic scales shown in Figure 4-2. The process for the landscape analysis is described in detail in Chapter 5.

4.2.2.1 Analyses of the Contributing Landscape and the Management Area

The analyses of the contributing landscape and the management area are similar. The difference in the analyses for these two geographic scales is more an issue of resolution than of approach. If the management area is smaller than the contributing landscape, the analysis of the management area can make use of more detailed information, such as detailed wetland inventories and ratings. Local jurisdictions can then develop a more detailed program and have better assurance that the risks to their wetlands are minimized. The same tools and methods, however, can be used at either geographic scale.

The purpose of the analysis at either scale is to develop an understanding of landscape processes that can affect wetland functions. This includes understanding the movement of water, nutrients, sediments, and toxic compounds, and how wetlands that function as habitat are affected by fragmentation of the landscape. It involves inventorying wetland resources, identifying where critical landscape processes occur, and determining how those critical processes have been modified by human activities. From this understanding, one can then determine how these landscape processes may have been changed in the past, and how they might change with future development.

There are two main goals of the landscape analysis. The first goal is to identify locations within the contributing landscape and the management area where landscape processes could be negatively influenced by human land uses (e.g., paving areas that provide groundwater recharge). When planning future changes in land use, these areas can be considered sensitive and in need of specialized management approaches because changes in these locations can be a major cause of cumulative impacts. These areas may not necessarily include only wetlands but may encompass important upland areas that influence wetlands (e.g., areas where groundwater is recharged or corridors of undisturbed uplands that connect wetlands).

The second goal is to identify areas where landscape processes have been degraded but could be repaired, such as through wetland restoration. Planning for restoration could help offset unavoidable impacts identified through the planning process.

This information is used during Step 2 (Prescribing Solutions) and Step 3 (Taking Actions).

4.2.2.2 Analyzing Wetlands at the Site Scale

The main goal of the analysis at the site scale is to understand the functions of an individual wetland and how that wetland interacts with the landscape. This analysis can occur at two different times in the planning and regulatory process: during comprehensive planning and during review of permits for individual projects.

If a local jurisdiction's program to protect and manage wetlands involves preservation or restoration, then individual wetlands will need to be analyzed. Information from the analysis can be used during comprehensive planning (Step 2) to identify those wetlands most suited for preservation and restoration.

The functions of individual wetlands are also often analyzed when permits are sought to alter a wetland. It is, therefore, important for local governments to establish what will be required for site-specific analysis of wetlands during Step 2, when administrative rules, guidance, or regulations are developed (Chapter 8). For example, the requirements should state what must be included within wetland reports and plans for compensatory mitigation. The local jurisdiction should also consider methods for assessing wetland functions and for establishing ratings, buffers, and mitigation ratios. Site-specific analysis is usually the responsibility of the applicant who is proposing changes to a specific wetland.

For further guidance on Step 1, Analyzing the Landscape and Its Wetlands, see Chapter 5 and Appendices 5-A through 5-C of this volume.

4.2.3 Step 2: Prescribing Solutions

Step 2 describes the processes by which local governments develop solutions to protect and manage wetlands within their jurisdiction. The goal of Step 2 is to identify means for incorporating the results of the landscape analysis in Step 1 into effective planning, regulatory, and non-regulatory tools. This is the step in which Smart Growth planning approaches, such as Green Infrastructure or Alternative Futures (discussed in Chapter 6), can be applied and when comprehensive plans, critical areas ordinances, shoreline management plans, restoration plans, and incentives for conservation are typically developed.

4.2.3.1 Prescribing Solutions at the Scale of the Contributing Landscape

To develop solutions for a contributing landscape, which often extends outside the regulatory authority of a local jurisdiction, the jurisdiction will need to coordinate with other, contiguous governments. In reality, however, adjacent jurisdictions may not share the same values or priorities. Because the ability of a local jurisdiction to plan for geographic areas outside of its purview may, therefore, be limited, this document only provides general guidance at this time.

For areas of the contributing landscape that fall within the management area, the process of prescribing solutions is the same as for the management area, as described below.

4.2.3.2 Prescribing Solutions at the Scale of the Management Area

Solutions for protecting and managing wetlands within the management area can be prescribed in many forms. Generally, they include policies contained within comprehensive plans or community plans; codes (such as zoning) and ordinances (including those for critical areas and clearing and grading); stormwater management plans; shoreline master programs; non-regulatory approaches, such as preservation and restoration plans; and incentives for conservation, such as tax relief.

The approach proposed here is to plan for future development and the protection of wetlands by analyzing different alternative scenarios (called Alternative Futures) in terms of their impacts on wetlands and landscape processes. These scenarios should include both general planning approaches, such as different patterns of zoning, and more specific approaches, such as different widths of buffers for wetlands with different ratings. The local government usually incorporates other factors into the scenarios based on the priorities of citizens for their communities. (See Chapter 6 for further discussion.)

The effects of the different scenarios can be compared and evaluated to determine which solution might reduce or limit the impacts to landscape processes. Analyses of scenarios are an important way to summarize detailed scientific information, and they can be very helpful in decision-making.

Step 2 is also the step at which a jurisdiction should ensure consistency between various policies, plans, and regulations administered by the jurisdiction that may influence wetland resources. For example, a grading code may have to be modified to reflect considerations for wetlands or their buffers.

4.2.3.3 Prescribing Solutions at the Site Scale

Prescribing solutions at the site scale involves developing ways to protect wetlands which require tailored protection that is different from the protection afforded to most other wetlands through critical areas regulations. These wetlands are often called "wetlands of local significance." They may include wetlands with a high value for recreation, aesthetics, potential for restoration, or potential as mitigation banks; or they may be crucial to supporting a landscape process, such as aquifer recharge.

The solutions for protecting these wetlands can be specified in advance by using policies in the comprehensive plan or community plans or even site-specific or wetland-type-specific regulatory language. For example, the City of Everett identified specific actions at individual wetlands at the mouth of the Snohomish River estuary that could be taken to restore landscape processes (City of Everett 1997). There was a high probability of success with an important increase in functions.

For guidance regarding tools for Step 2, Prescribing Solutions, see Chapters 6 through 9 of this volume.

4.2.3.4 Characterizing the Risk from Proposed Solutions

A characterization of risks should be used to evaluate the different solutions being suggested for protecting and managing wetlands. Such a characterization provides a way to develop, organize, and understand the decisions being made about future land uses. It also enables decision-makers and the public to make more informed decisions about land uses and wetland resources. Solutions that cause a higher risk to the wetland resource because they are driven by other societal needs can be balanced by solutions that reduce the risks (e.g., through restoration). Avoiding impacts and maintaining functions, however, is generally more cost effective and less risky than trying to replace functions (see Volume 1 and Chapter 6 of this volume for further discussion).

For guidance on characterizing the risk from proposed solutions see Chapter 10 of this volume.

Prescribing solutions incorporating shoreline planning

Solutions for protecting and managing wetlands can be provided in the context of both the Growth Management Act (GMA) and the Shoreline Management Act (SMA). The goal of Step 2 is to incorporate the results of the landscape analysis in Step 1 into plans, regulations, or other actions that will protect wetlands.

The SMA was adopted by Washington's public in a 1972 referendum "to prevent the inherent harm in an uncoordinated and piecemeal development of the state's shorelines." One of the policies in the SMA is to protect shoreline natural resources including "…the land and its vegetation and wildlife, and the water of the state and their aquatic life…" Some wetlands, therefore, are protected by both the SMA and the GMA. In 1995, the Legislature amended the GMA and the SMA to partially integrate the two statutes (1995 c 347). The amendments incorporate the goals and policies of the SMA as the 14th goal of the GMA; specifically designating the goals and policies of a shoreline master program (SMP) as an element of a local government's comprehensive plan, and designating the balance of the SMP as a segment of the jurisdiction's development regulations (RCW 36.70A.480). In 2003 the Legislature added a requirement that new SMPs must provide a level of protection to critical areas within shoreline jurisdiction that is "at least equal" to the level of protection provided to critical areas under the local government's critical areas ordinances.

On December 17, 2003, Ecology adopted new guidelines for SMPs to implement the revisions to the SMA. The guidelines provide a process for local jurisdictions to implement the policy of the SMA of protecting natural resources of shorelines through the protection and restoration of ecological functions (and environmental processes) necessary to sustain these natural resources. The guidelines specifically state that effective management of shorelines depends on sustaining the functions provided by: 1) ecosystem-wide processes (i.e., flow and movement of water, sediment, and organic materials and movement of fish and wildlife; these are called landscape processes in this volume); and 2) individual components and localized processes such as those associated with shoreline vegetation, soils, and water movement through the soil and across the land [WAC 173.26.201(2)(c)]. The guidelines incorporate the use of scientific knowledge of environmental processes (physical, chemical, and biological processes) that affect the ecological functions of shorelines (and their associated wetlands). Thus, the guidelines for preparing SMPs include an assessment of many of the same environmental processes that are outlined in this volume.

Further, the new guidelines require that SMP policies and regulations ensure "no net loss" of ecological functions necessary to sustain natural ecosystems of shorelines. Updated SMPs must regulate new development in a manner that is protective of existing ecological functions and provide policies that "promote restoration of impaired ecological functions" (WAC 173.26.201(2)(c) and (f)).

The process for preparing an updated SMP is compatible with the four-step framework outlined in this document. The rules (WAC 173.26.201(3)) spell out a general process for updating SMPs that includes: comprehensive inventory of shoreline conditions; characterization and analysis of functions and ecosystem-wide processes; development of shoreline policies, regulations, and environment designations; and development of goals, policies, and actions for the long-term restoration of impaired shoreline ecological functions. The guidance for analyzing the aquatic resources, developing solutions, implementing the solutions, monitoring and adaptive management provided in this document can prove useful to jurisdictions planning under the SMA.

4.2.4 Step 3: Taking Actions

Step 3 ensures that the solutions developed and adopted in Step 2 are effectively implemented through taking actions at the different geographic scales. Examples of taking actions include:

- Implementing regional, subarea, or community plans on the ground
- Applying critical areas and clearing and grading ordinances at specific wetland sites when a development is proposed
- Restoring or preserving wetlands identified in a restoration plan through a landscape analysis
- Setting up a Public Benefit Rating System to provide tax relief for landowners with wetlands (see Chapter 9 for more information)

4.2.4.1 Taking Action at the Scale of the Contributing Landscape

Taking action at the scale of the contributing landscape requires adequate funding and coordination over time. Although the benefits can be great if the solutions are carried out, the challenges are great as well. For example, of the three regional plans that have been developed to protect wetlands—the Everett Snohomish Estuary Wetland Integration Plan (SEWIP) (City of Everett 1997), the Mill Creek Special Area Management Plan (SAMP) (U.S. Army Corps of Engineers 1997), and the Port of Skagit Wetland Industry Negotiations (WIN)—only one (Skagit WIN) was ever adopted and implemented. (For more information on the Skagit WIN contact the Port of Skagit County in Burlington, Washington.)

4.2.4.2 Taking Action at the Scale of the Management Area

Taking action to implement plans, regulations, and non-regulatory approaches adopted by a jurisdiction for its management area is critical to protecting wetlands. The scientific literature reviewed for Volume 1 indicated that one of the major reasons why the functions and values of wetlands continue to be degraded is a lack of resources to implement and monitor proposed solutions.

In the case of a critical areas ordinance for wetlands, an adequate number of staff is needed. The staff should be trained to review permit proposals and enforce the conditions placed on those proposals to ensure that wetlands are protected as planned. This holds true especially for compensatory mitigation. Chapter 6 of Volume 1 highlights the fact that many compensation projects designed to replace wetland functions lost through development have failed in part because of a lack of regulatory oversight and follow-through. Likewise, plans that call for restoration need staff and sources of funding to implement the plans, acquire sites, and monitor the efforts.

4.2.4.3 Taking Action at the Site Scale

Taking action at the site scale means applying the management measures identified for a specific wetland; for example, an individual wetland that is restored using a plan developed for a management area. Implementation at the site scale also requires monitoring the compliance and effectiveness of compensatory mitigation or non-regulatory actions taken at individual sites.

For further discussion of Step 3, Taking Actions, see Chapter 11 of this volume.

4.2.5 Step 4: Monitoring

Monitoring at all three geographic scales (contributing landscape, management area, and site) should be an integral part of a strategy to protect and manage wetlands. It is a key step in determining whether cumulative impacts have actually been minimized during Step 3, Taking Action. Monitoring should address the following central question: *Are the actions taken by a local jurisdiction effectively protecting or restoring the functions and values of the wetlands within its purview and thereby addressing cumulative impacts?*

Local jurisdictions cannot determine whether their solutions (developed in Step 2 and implemented in Step 3) are actually protecting wetlands without collecting data that monitor the success of their approach at the three geographic scales. Monitoring whether adequate protection has been achieved, followed by any needed corrective action, is especially critical. All the information collected to date and reviewed in Volume 1, indicates that there is continued loss of wetlands and their functions and values (cumulative impacts).

Monitoring associated with assessing the protection and management of wetlands by local jurisdictions can be divided into three categories:

- **Monitoring the effectiveness of actions taken to protect and manage wetlands** to determine how well the overall approach (including all solutions) is meeting the goals to protect and manage wetlands at all geographic scales
- **Monitoring the actions taken to implement** the regulatory and non-regulatory solutions developed at all geographic scales
- **Monitoring trends** regarding changes in landscape processes and the level of performance of the functions provided by wetlands at the site scale (i.e., monitoring cumulative impacts)

If the functions and values of wetlands are not adequately protected, managers need to know whether this results from inadequate implementation, inadequate standards, or inadequate strategies. Therefore, all three aspects of monitoring are important in providing feedback to guide future decision-making.

For further discussion of Step 4, Monitoring, see Chapter 12 of this volume.

4.2.6 Adaptive Management

Adaptive management—the feedback loop—is based on a review of the information collected through the monitoring step and a determination of what changes are necessary to improve protection when goals are not met. In this way, future management, policies, and regulations can be more effective in protecting the wetland resource (Washington State Joint Natural Resources Cabinet 1999). Scientists agree that some of the continued degradation of the functions and values of natural systems such as wetlands is a result of a lack of monitoring and adaptive management (Dale et al. 2000). This aspect of protecting and managing wetlands is, therefore, vital to successfully protecting wetlands over time.

The key element of adaptive management is a commitment to periodically revisit the four steps in the framework described earlier. Monitoring should provide new data and information that feed back into the analysis the landscape and its wetlands (Step 1). As the data are analyzed, new information can be generated that may require changing the solutions prescribed (Step 2) and the actions that need to be taken (Step 3). The effectiveness of the new solutions and actions then also needs to be monitored (Step 4), and the cycle repeated over time.

For further discussion of Adaptive Management, see Chapter 12 of this volume.

Chapter 5

Analyzing the Landscape and Its Wetlands

5.1 Introduction

This chapter describes the first step (Analyzing the Landscape and Its Wetlands) in the four-step framework for the program to protect wetlands outlined in Chapter 4. It describes how the landscape, and the wetlands found within it, might be analyzed by a local jurisdiction (see Figure 5-1). Section 5.2 summarizes the importance of the interaction between landscape processes and wetland functions because this information may not be common knowledge for some planners. Section 5.3 provides background on the goals of landscape analysis, because this is a relatively new approach in protecting and managing wetlands. Section 5.4 describes the basic questions that should be answered when analyzing the contributing landscape and management area to assist with decision-making. Identifying important questions should enable local governments to choose the most appropriate method to analyze the landscape for their jurisdiction. Any method or methods that provide answers to these questions can be used. Section 5.5 addresses analyses at the scale of individual wetlands.

The questions discussed in this chapter are derived from the work on environmental processes nationally and in the Pacific Northwest done by Bedford (1996, 1999), Beechie and Bolton (1999), Booth (1991), Brinson (1993), Gersib (2001), Horner (1986), Horner et al. (1996), LaBaugh et al. (1987), Naiman et al. (1992, 1993), Naiman and Rodgers (1997), Stanley and Grigsby (2003), Winter (1983, 1986, 1988, 1989, 1992), and Ziemer and Lisle (1998).

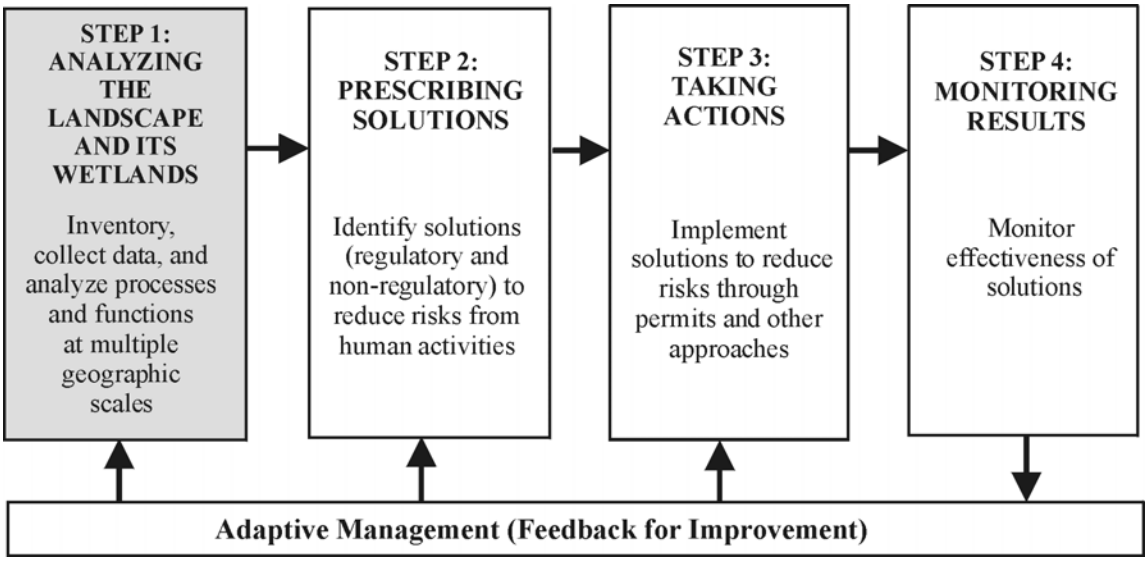

Figure 5-1. Step 1 in the process of protecting and managing wetlands is to analyze wetland resources (shaded box).

Why do we analyze more than just wetlands?

The synthesis of current science (Chapter 2 in Volume 1) indicates that the functions performed by wetlands are controlled by processes that may occur in other parts of the landscape as well as at the site of the wetland itself. To protect and manage the functions and values of wetlands, we therefore need to understand how changes to these wider-scale processes can impact wetlands. In this way, cumulative impacts to wetlands can be minimized.

The following appendices provide additional information and details to help the reader more fully understand the landscape analysis described in this chapter:

Appendix 5-A identifies some of the existing sources of data that can be used to answer the questions when analyzing the landscape and its wetlands.

Appendix 5-B summarizes numerous literature sources that provide more detail on how to analyze environmental processes at the contributing landscape, management area, and site scales.

The reader is also directed to a web site describing a method for completing a landscape analysis for aquatic systems being developed by Ecology (http://www.ecy.wa.gov/programs/sea/landscape/). The analysis uses existing geographic data to characterize environmental processes at the larger landscape scale, and helps identify the relationship of these processes to the functions of wetlands and other aquatic resources.

The method being developed can help local governments protect and manage wetlands as well as other aquatic resources. It is useful for both planning purposes as well as regulatory and non-regulatory applications at the site scale. Currently, however, the method does not address the analyses needed to protect and manage wildlife. This gap will be addressed in the near future as the departments of Fish and Wildlife and Ecology work together to expand the wildlife component of the analysis.

The questions that need to be addressed in the analysis of the landscape and its wetlands apply regardless of the methods used to analyze the resource. The method being developed by Ecology is one way they can be answered.

The web site for Ecology's method for analyzing the landscape is updated periodically as changes and innovations are incorporated. It is currently being revised following application in several jurisdictions. Even when undergoing revisions, the web site is useful in understanding the basic principles, information sources, and steps used in Ecology's method to analyze the landscape and apply the results in context of land-use planning.

5.2 Landscape Processes and Their Influence on Wetlands and Their Functions

Chapter 2 in Volume 1 describes how landscape processes interact with climate, topography, and surface geology to determine the biological, physical, and chemical characteristics (structure) of wetlands and other aquatic resources. The structure of wetlands (e.g., the soils, plant species, configuration of inlets and outlets, etc.) then has a direct influence on the type and level of functioning within wetlands. The sequence, however, does not go only in one direction. Some wetland functions can in turn influence the structure of other wetlands and landscape processes (e.g., when wetlands provide habitat for beavers; see Figure 5-2).

Terms used in this document to refer to environmental factors

Surface and subsurface water flows through the landscape within drainage systems. These drainage systems are often called basins, sub-basins, watersheds, or river basins depending on the size of the area. In this document, drainage systems are generally referred to using one of two terms:

- ***Watershed*** **-** A geographic area of land bounded by topographic high points in which water drains to a common destination.
- ***Contributing basin*** **-** The geographic area from which water drains to a particular wetland.

Environmental factors that affect wetland functions can occur at different geographic scales. In this document two scales are used.

- ***Landscape processes*** **-** Environmental factors that occur at larger geographic scales such as basins, sub-basins, and watersheds. Processes are dynamic and usually represent the movement of a basic environmental characteristic such as water, sediment, nutrients and chemicals, energy, or animals and plants. The interaction of landscape processes with the physical environment creates specific geographic locations where groundwater is recharged, flood waters are stored, stream water is oxygenated, or pollutants are removed, and wetlands are created.
- ***Site processes*** **-** Environmental factors that occur within the wetland itself or within its buffer. The interactions of site processes with landscape processes define how a wetland functions.

In the Pacific Northwest, the landscape processes that are often associated with wetland functions include:

- The movement of **water** (surface and subsurface) through the contributing landscape and at the wetland site itself
- The movement of **sediment**
- The movement of **nutrients** and other chemicals (salts, toxic contaminants)
- The movement of **energy** in the form of carbon (plant and animal material)
- The movement, population dynamics, and habitat use of **wildlife**
- The dispersal of **plants**

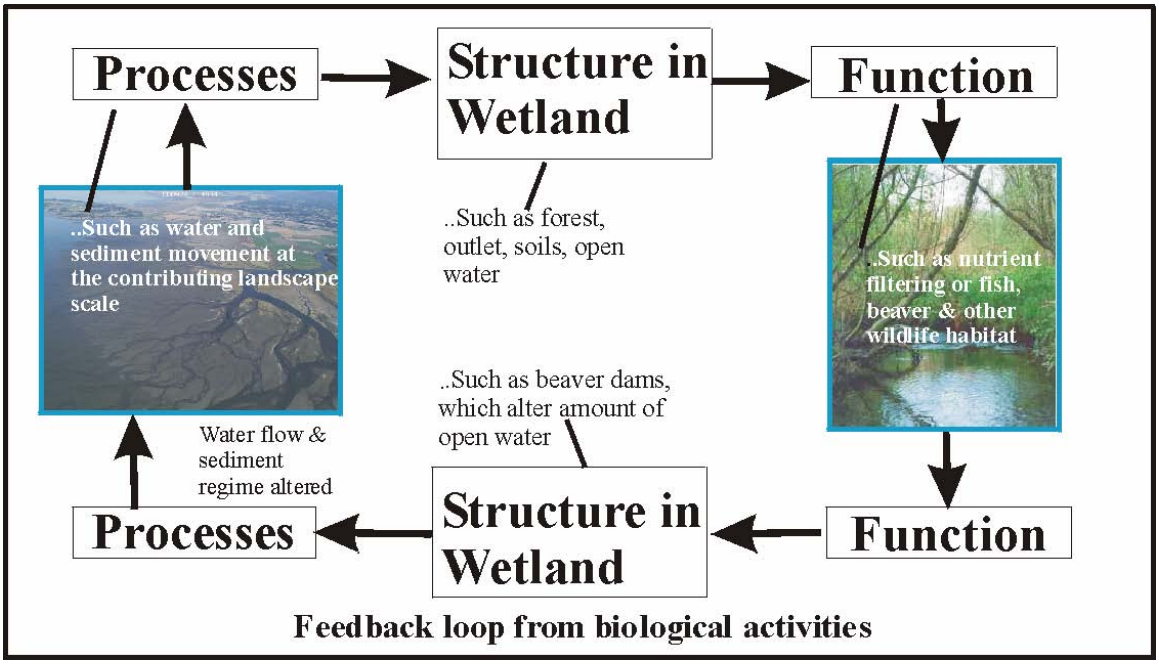

Figure 5-2. Wetlands and their functions are an expression of landscape processes. Wetland functions can in turn modify the landscape processes.

As an example, a wetland may function to support a rich food web in the aquatic resources downstream by exporting large quantities of plant material. In order to provide this function, the wetland needs to have the following:

- Water with adequate nutrients coming into the wetland
- Good exposure to sunlight
- A way for the plant material to pass from the wetland into downstream aquatic resources

The major processes that control the export of food are the movement of water to and from the wetland, and the movement of nutrients into and within the wetland. Thus, human alterations in the movement of water and nutrients into the wetland from the contributing landscape may change how the wetland supports the food web downstream.

5.3 Goals and Objectives of Analyzing the Landscape

The primary goal of a landscape analysis is to develop an understanding of where landscape processes occur and where they are particularly sensitive to human disturbances. As mentioned previously, changes to landscape processes will often result in changes to the functions in wetlands. An understanding of the geographic locations where processes are most sensitive to change is needed to identify appropriate and effective solutions for protecting wetlands and their functions (these solutions are then developed in Step 2 of the framework). Understanding environmental factors in the landscape is basic to planning how humans should use the land in the future, where they should preserve it, or how they might restore it.

Landscape analysis can support land-use planning, including comprehensive planning, because it provides a basis for understanding the future impacts of different zoning configurations and development scenarios. The following objectives for a landscape analysis help achieve this goal:

- Identifying which parts of the landscape provide essential environmental processes (landscape processes)
- Identifying the range of disturbances that affect landscape processes, and whether they are caused by human activities or natural disturbances
- Identifying which geographic areas are most susceptible to these disturbances, and therefore pose environmental constraints to land uses in these settings
- Determining how the landscape processes and the geographic areas that provide these processes influence wetlands and their functions

These objectives can be met by answering the questions posed in the following section.

The objectives apply to analyzing both the contributing landscape and the management area. Landscape processes are not geographically constrained by political boundaries. The reason for presenting a framework that separates the contributing landscape into two geographic units (the management area and the contributing landscape outside the management area) is to simplify the task of protecting and managing the wetland resources. Landscape processes and wetlands that occur within a jurisdictional boundary can be protected and managed by that jurisdiction. Protection outside the jurisdictional boundary will require a cooperative effort by several jurisdictions.

5.4 Questions that Can Be Used to Guide an Analysis of the Contributing Landscape and the Management Area

The questions listed below can be used to guide an analysis of the landscape and are phrased so the answers can be used to meet the goals and objectives described above. Each question is discussed in detail in the subsections that follow.

The questions that direct a landscape analysis are similar for both the contributing landscape and the management area. As previously mentioned, the difference in the analysis for these two geographic scales is more an issue of resolution than a different approach. If the management area is smaller in size than the contributing landscape, the analysis of the management area can make use of more detailed information. Local jurisdictions can then develop more detailed plans and be provided a better assurance that the risks to their wetlands are minimized. The same tools and methods, however, can be used at either geographic scale.

- **Question 1.** What are the landscape processes in the contributing landscape in the absence of human alterations (i.e., before they were altered by human activities on the land), and where are they located geographically?
- **Question 2.** What are the relationships between these original landscape processes and the wetlands and their functions in the management area?
- **Question 3.** What alterations to landscape processes have occurred, and how have these changes affected the wetlands and their functions?
- **Question 4.** What geographic areas are currently important for maintaining landscape processes and can be impacted by future activities and growth?
- **Question 5.** What measures can be used to protect and restore landscape processes in order to protect and restore the wetlands and their functions?

These questions should be answered by local jurisdictions prior to completing Step 2, Prescribing Solutions (e.g., developing critical areas ordinances, shoreline master programs, restoration programs, etc.), and Step 3, Taking Actions (i.e., implementing the solutions identified in Step 2), in the four-step framework. Although each question is directed toward wetlands and their functions, some of the landscape processes analyzed in answering these questions involve other aquatic resources and critical areas and can be used to help other planning efforts.

5.4.1 Question 1. What are the landscape processes in the contributing landscape in the absence of human alterations, and where are they located geographically?

The focus of this question is on processes that affect wetlands in the management area, but it can apply to all landscape processes in the contributing landscape because they are important factors for all natural resources and other critical areas. Understanding the landscape processes that were present in the absence of human disturbances defines the baseline conditions against which changes can be compared. In addition, it helps to identify the aspects of processes that are essential to maintaining current functions of wetlands.

Understanding the environmental processes in the absence of human disturbance is important even if recreating the "undisturbed conditions" is not a goal of the planning process.

This question can be answered by identifying and mapping the landscape processes that support or maintain wetlands and their functions. In general, these processes will fall into the following categories: the movement of water, sediment, nutrients, energy, and wildlife, as well as physical, chemical, and biological interactions that can occur at the watershed and sub-basin scale. To identify these processes, the jurisdiction will need to consider the historic condition and location of the following:

- Drainage patterns of surface water – how surface water reaches the wetlands (e.g., areas contributing water to the wetlands including streams, culverts, stormwater outfalls, and sheet flow)
- Flow paths of groundwater – where groundwater is recharged and discharged and where discharge has created wetlands
- Sediment and its path through the contributing landscape – likely sources of sediment, areas where sediment is deposited, and ways that sediment moves through the landscape to the wetlands
- Nutrients and their path through the contributing landscape – likely sources of nutrient inputs, areas where nutrients would be removed, and pathways for nutrients reaching the wetlands
- Corridors along which wildlife moves and plants are dispersed

Sources for this information include soils maps, aquifer recharge maps, stream inventories, topographic maps, resource/habitat maps from state and federal agencies, zoning maps of active agricultural lands, or even environmental documents such as environmental impact statements. Note that some of these landscape processes may occur at a scale much larger than the extent of the historic wetlands and may extend throughout the contributing landscape.

5.4.2 Question 2. What are the relationships between these original landscape processes and wetlands and their functions in the management area?

Answering this question requires analyzing the connections between the location of landscape processes and existing and historic wetland resources. The most important process to consider is where on the landscape water reaches the surface, or where surface water is slowed down enough to be ponded. Generally wetlands will form in these locations. For example, extensive peat deposits at the base of a slope where groundwater surfaces would indicate a probable location of wetlands. Topographic depressions in a floodplain would indicate locations where floodwaters can be stored and where wetlands also often occur.

The connections between wetlands and landscape processes are very specific to the topographic, geologic, and climatic conditions of an area. If an existing method to analyze the landscape, such as that being developed by Ecology, is not used, local experts will need to be consulted to develop an understanding of the links between wetlands and landscape processes.

5.4.3 Question 3. What alterations to landscape processes have occurred, and how have these changes affected wetlands and their functions?

Answering this question will require understanding where the following alterations have occurred:

- Changes to water flow. For example, areas where:
  - Surface water flow has been diverted, channelized, or culverted
  - Subsurface flow has been converted to surface flow
  - Increased flooding occurs
  - Stormwater management facilities have been installed
- Changes in the sources and transport of sediment. For example, areas where:
  - Active land clearing, construction activities, or agricultural practices occur
  - Sediments are deposited
  - Streams are entrenched
  - There is excessive bank erosion
  - Sediment enters streams from roads and roadside ditches

- Changes in water quality. For example, areas with:
  - Increased input and transport of nutrients (may be associated with sediment sources)
  - Increased input and transport of toxic compounds and pathogens
  - Biological impacts such as closure of shellfish beds or an increase in harmful algal blooms
- Wetlands have disappeared (e.g., from filling or ditching and draining)

Answering this question provides an understanding of how landscape processes and wetland resources have been altered. It is not necessary to measure or quantify changes in landscape processes directly to answer this question. Instead this can be accomplished by comparing maps of the disturbed conditions (generated through the analysis for this question) to the undisturbed conditions as mapped in the analysis needed to answer Question 1. Changes in processes can be inferred from specific indicators of change listed in the bullets above.

For example, the most readily available information on changes in types of land use may be through comparison of historic aerial photographs to current conditions. Such a comparison can illustrate changes such as conversion of forested lands to an agricultural or a built condition; conversion of agricultural lands to a built condition; changes in land use from low to high density or residential to commercial/industrial uses; and so on. Additional data on water quality from monitoring reports, information from surveys of the numbers and types of road crossings on streams and rivers, and/or information on the physical alteration of streams and rivers (e.g., ditching, diking, etc.) can all serve as indicators of changes in processes.

5.4.4 Question 4. What geographic areas are currently important for maintaining landscape processes and can be impacted by future activities and growth?

Once a jurisdiction has identified the areas where landscape processes historically occurred and where they have been changed, it is possible to identify those areas where landscape processes still occur today. This information can be used to predict where additional changes to processes and wetlands might occur from future activities. The purpose is to identify areas where the movement of water, sediment, nutrients, energy, and wildlife are particularly sensitive to additional human activities and disturbances.

The following are some human activities occurring in areas that are particularly sensitive:

- Filling in floodplains alters the movement of water and especially flood storage
- Paving in areas where groundwater is recharged resulting in reduced infiltration and baseflow to streams

- Building roads through the remaining vegetated corridors reduces the movement of animals and increases the potential invasion of unwanted plant species (Vegetated corridors are sensitive to being fragmented)

5.4.5 Question 5. What measures can be used to protect and restore landscape processes in order to protect and restore wetlands and their functions?

Answering this question is primarily an analytical process that relies on data and information collected in the previous questions. There are two objectives associated with this question. The first is to identify areas that have not yet been altered but are critical to maintaining processes and functions—the sensitive areas identified in Question 4. These should be managed to minimize the potential impacts of human activities through regulatory and non-regulatory means. The second is to identify where landscape processes have been altered but can be restored. Chapters 6 through 9 of this volume discuss in detail the regulatory and non-regulatory approaches that can be used for protection and restoration.

5.5 Questions that Can Be Used to Guide an Analysis of Individual Wetlands

The questions listed below can be used to guide an analysis of individual wetlands. The questions are phrased so the answers can be used to meet both regulatory and non-regulatory needs to protect and manage wetlands. The landscape analysis described in the previous section is appropriate for the development of land use and other plans. It does not, however, provide enough detail for making decisions about individual wetlands, either permit decisions which are site-specific or site-specific decisions about restoration or preservation. Questions 6 and 7 reflect analyses that are usually done during the planning process and in conjunction with the landscape analysis done for Questions 1-5. Question 8 addresses analyses that are most often done when proposals are submitted for altering specific wetlands.

- **Question 6.** What wetlands are currently performing functions that are associated with important processes identified in the landscape analysis?

- **Question 7.** What degraded wetlands or former wetlands are suitable for restoring landscape processes identified in Question 3?

- **Question 8.** What are the functions of individual wetlands that need to be protected, preserved, or managed?

5.5.1 Question 6. What wetlands are currently performing functions that are associated with important processes identified in the landscape analysis?

Answering this question is primarily an analytical process that relies on data and information collected in Question 4. The purpose is to identify specific wetlands where the movement of water, sediment, nutrients, energy, and wildlife are particularly sensitive to additional human activities and disturbances. These wetlands will be a subset of the sensitive areas identified in Question 4, and they should be specifically highlighted in any general plan to protect and manage wetlands.

For example, headwater wetlands are very important in desynchronizing flood flows in downgradient areas. This desynchronization maintains the landscape process of water flow, and protecting this function in headwater wetlands is important for the entire watershed downstream.

5.5.2 Question 7. What degraded wetlands or former wetlands are suitable for restoring landscape processes identified in Question 3?

Opportunities for restoration can be identified by developing a map of wetlands that have been degraded, and furthermore that may no longer meet the definition of a wetland. This is accomplished using hydric soils, wetland inventories, and land-use maps. The locations where these former or degraded wetlands intersect the areas where landscape processes occur (from Questions 1 and 4) are the areas best suited for restoration. This information is the basis for developing regional restoration plans, developing mitigation banks, and developing an understanding of the type of compensatory mitigation that is appropriate for permitted alterations to existing wetlands.

5.5.3 Question 8. What are the functions of individual wetlands that need to be protected, preserved, or managed?

The functions present in a wetland need to be understood in order to apply protective measures that will adequately protect these functions, such as buffers and appropriate mitigation plans. Not all wetlands provide the same functions or function at the same levels (see Chapters 2 through 4 in Volume 1 for further discussion). The analyses of functions of individual wetlands are usually done as part of permitting for actions that could affect that wetland.

Most analyses of wetlands at a specific site use rapid approaches that assess a range of wetland functions and values. Many methods have been developed in the last decade to analyze wetland functions and values, and these have been summarized in numerous

compilations (e.g., Hruby 1999, Bartoldus 1999, and the Army Corps of Engineers Ecosystem Management and Restoration Information System http://el.erdc.usace.army.mil/emrrp/emris/ go to Index, Wetland Procedure Descriptions).

In addition, Ecology has developed several methods that can be used for the analysis of functions at the site scale. The *Washington State Wetlands Rating System for Eastern Washington - Revised* (Hruby 2004a) and the rating system for western Washington (Hruby 2004b) were developed to categorize wetlands based on their sensitivity to disturbance, how difficult they may be to replace through compensatory mitigation, the rarity of the wetland type, and the groups of functions they provide.

Methods for Assessing Wetland Functions (Hruby et. al. 1999, 2000) (also called Washington State Wetland Functions Assessment Method or WFAM) provides more detailed information on up to 15 specific functions that a wetland performs. Both the rating systems and the methods for assessing functions do not address other benefits wetlands provide such as aesthetics, provision of educational and recreational opportunities, etc. WFAM is currently available for a subset of wetland types in both eastern Washington (Hruby et al. 2000) and western Washington (Hruby et al. 1999).

Other methods that have been developed for analyzing individual wetlands in Washington State include the *Wetland Functions Characterization Tool for Linear Projects* from the Washington State Department of Transportation, which characterizes functions as "probably present" or "probably not present" and as "principal" or "secondary" functions (Null et al. 2000). A brief description of these and other assessment methods that are often used in the state is provided in Appendix 5-B.

In some cases all the wetlands in a basin or sub-basin are analyzed in advance of any actions as part of a regional plan using one of the "rapid" methods described above. This information is used to guide planning by identifying up front those individual wetlands that should not be altered because they perform important functions that cannot be replaced. Wetlands are also identified that do not function well. These can be identified as suitable for development with appropriate compensation. Potential or recommended mitigation sites can also be identified during this planning process. Examples from the Puget Sound area include the Mill Creek Special Area Management Plan or SAMP (U.S. Army Corps of Engineers 1997) and the Everett Snohomish Estuary Wetland Integration Plan or SEWIP (City of Everett 1997).

Chapter 6

Prescribing Solutions: Landscape-Based Land-Use Plans

6.1 Introduction

This chapter presents approaches to developing plans and policies that incorporate the information collected during Step 1 of the four-step framework—the analysis of the landscape and its wetlands—as described in Chapter 5. Developing plans and policies is part of Step 2 (Prescribing Solutions) in the framework of a wetland management program (Figure 6-1).

Plans and policies are enhanced by information generated in Step 1, which involves analyzing the role that wetlands play in landscape processes. Landscape processes both maintain and interact with wetlands and the functions they perform. Landscape processes can include physical processes such as those that maintain hydrology and the physical stability of shorelines; chemical processes such as those that maintain or degrade water quality; and ecological processes such as those that maintain habitats and species.

The results of these landscape analyses are used in Step 2 to identify solutions that reduce the risk of human activities that degrade or eliminate wetlands and landscape processes.

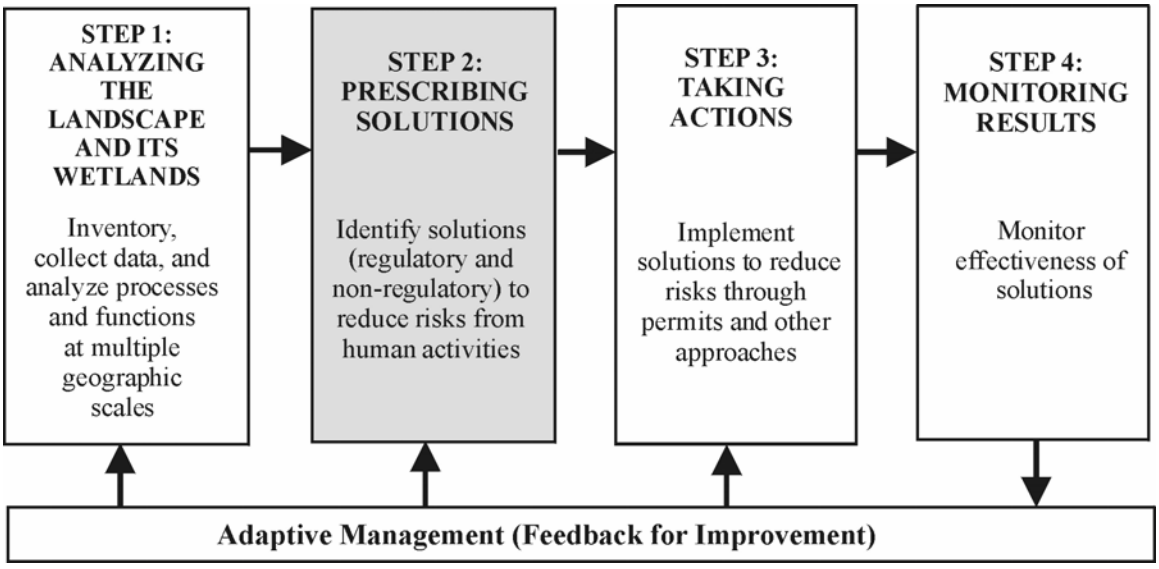

Figure 6-1. Developing plans and policies fits into Step 2 within the four-step framework recommended for protecting and managing wetlands (shaded box).

This chapter begins with a brief overview of planning and the Washington State Growth Management Act (GMA) (Section 6.2). It then describes the importance of using landscape analysis and approaches (at the appropriate scales) when initiating and completing planning processes (Section 6.3). Next, Smart Growth is introduced (Section 6.4); the concepts of which form the foundation for two complementary planning applications called Green Infrastructure and Alternative Futures which are described in some detail. These approaches have been used as reliable frameworks for the inclusion of landscape analysis and perspectives within both local (such as subarea plans) and comprehensive planning processes (described in Chapter 7). The chapter concludes (Section 6.5) with a discussion of the fiscal benefits of maintaining landscape processes by protecting critical areas such as wetlands, floodplains, streams and riparian areas, nearshore areas, etc.

6.2 Overview of Planning and the GMA

Land-use planning, in the context of resource management, is the formalized process by which jurisdictions identify what can or cannot occur on lands within their regulatory authority. In Washington State, land-use planning is implemented at a local (county or city) level of government and is directed by the Growth Management Act (GMA), with state agency technical assistance and oversight.

In 1990 the Washington State Legislature passed the GMA (RCW 36.70A) to guide local jurisdictions in their land-use planning efforts. The GMA dictates that counties and cities with certain characteristics must fully plan for future growth (RCW 36.70A.040). (Chapter 2 of this volume provides an overview of the GMA and a review of Hearings Board and court cases relating to the GMA, critical areas, and best available science.)

The GMA identifies goals to be used by local governments to "guide" the development of comprehensive plans. A full range of actions is included, such as concentrating development to limit urban sprawl; coordinating infrastructure for transportation; avoiding incompatible uses while maintaining the extraction of natural resources from forests and mines and agricultural production on designated lands of long-term commercial significance; as well as protecting the environment and the quality of life in the state. Cities and counties planning under the GMA have responded to these mandates by developing or updating their comprehensive plans and the codes and ordinances that implement the plans.

The planning process should begin with an understanding of existing natural resources (e.g., wetlands, floodplains, riparian areas, etc.) and the functions they provide, as well as the broader landscape processes with which they interact. Once these have been identified, they should be protected through comprehensive plans, other local plans, and the regulations and management practices that implement the plans.

Planning concepts and approaches described in this chapter (Smart Growth, Green Infrastructure, and Alternative Futures) use landscape-scale information to evaluate possible scenarios for future use and management of the land. They incorporate

alternative approaches for meeting future community needs while protecting ecosystems. The general objective of these approaches is to help identify options that both minimize environmental impacts and use the functions (services) provided by the ecosystems that exist within a healthy landscape. Wetlands, for example, will retain and slow floodwaters and recharge both stream flow and aquifers – environmental functions which engineering cannot easily or inexpensively replace. Good planning is therefore vital for protecting ecosystems, including critical areas and the functions they provide, as well as saving money for the community in the long run.

The planning approaches described below can be used as a basis for revising comprehensive plans or subarea plans, developing watershed protection and restoration plans, and supporting other planning and management efforts. They also provide a pragmatic approach for actively engaging the public by incorporating their direct input in the evaluation phase and by participating in making decisions about the future of their communities and surrounding landscapes.

Factors to consider when making land-use decisions affecting the future

In the paper *Ecological Principles and Guidelines for Managing the Use of Land* by V.H. Dale et al. (2000), scientists from around the country collaborated to identify factors to consider when making land-use decisions. These factors include the following:

1. Examine the impacts of choices in a regional (or landscape) context

2. Plan for long-term change and unexpected events

3. Preserve rare landscape elements, critical habitats, and associated species

4. Avoid land uses that deplete natural resources over a broad area

5. Retain large contiguous or connected areas that contain critical habitats

6. Minimize the introduction and spread of non-native species

7. Avoid or compensate for the effects of development on ecological processes

8. Implement land use and land management practices that are compatible with the natural potential of the area

The paper provides guidance for applying each of these factors to the planning process. They note that the mobility of human activities is more flexible (within limits) than the mobility of important landscape processes and ecosystem functions. Therefore, ecological constraints (the need to manage landscape processes for the long term) can be used as the primary consideration in land-use planning. The planning sequence they suggest is to first plan for maintaining water and biodiversity; then for cultivation, grazing, and the harvesting of wood products; then for managing sewage and other wastes; and finally for the placement of homes and industry. (The goals in the list above are also listed in Chapter 1 and should be considered throughout the four-step framework for protecting and managing wetlands and other critical areas.)

6.3 The Importance of Incorporating a Landscape Perspective in Planning

Land-use planning has traditionally focused on human actions implemented through management decisions at the level of the individual site or parcel. It has done so without always considering what is needed to protect environmental processes and wetlands at the landscape level (Dale et al. 2000). The synthesis of the science in Volume 1 indicates that the lack of incorporating information about the landscape in decisions made about land use, including those involving wetlands and their functions, is a major deficiency. For example, Volume 1 concludes that cumulative impacts lead to the degradation of wetlands and other natural resources. This results in the loss of landscape and watershed processes over time. A cumulative impact is "*…the impact on the environment which results from the incremental impact of the action when added to other past, present, and reasonably foreseeable future actions...Cumulative impacts can result from individually minor but collectively significant actions taking place over a period of time"* (Council on Environmental Quality 1997 http://ceq.eh.doe.gov/nepa/regs/ceq/1508.htm#1508).

Volume 1 goes on to state that regulatory programs that are based on a case-by-case approach and a lack of consistency between jurisdictions are two of the causes of cumulative impacts. Studies cited in Volume 1 found that decision-making that only considers individual projects without taking into account the larger landscape does not address cumulative effects (Johnston et al. 1990, U.S. Environmental Protection Agency 1999, Dale et al. 2000). This is especially significant for landscape processes that occur across jurisdictional boundaries (i.e., processes within the contributing landscape as depicted in Figure 4-2 in Chapter 4 of this volume).

One of the solutions for reducing cumulative impacts in the future, therefore, is developing plans and policies that incorporate information on larger landscape changes on these ecosystems and their respective landscape processes. Through analyses using data generated at this scale, local governments gain an understanding of where processes and functions occur, the interactions between ecosystems and the surrounding landscape, and how land uses may affect them.

With this knowledge comes the ability to minimize cumulative impacts to processes, functions, and resources by developing plans, policies, and setting clear management objectives that affect growth patterns. These can dictate which areas will be most fully protected and which may be degraded or remain in a degraded condition.

Plans, policies, and management objectives can in turn initiate protection programs that go beyond case-by-case decision-making by considering the larger landscape. For example, comprehensive planning based on landscape information can serve as the platform for critical areas ordinances, clearing and grading ordinances, zoning designations, shoreline master programs, protection measures through the Endangered Species Act, as well as non-regulatory restoration and preservation programs.

Local governments, therefore, benefit from having an understanding of key landscape processes and the functions that networks of critical areas provide. Landscape information can identify the capacity of natural resources like wetlands to provide important services to communities such as maintaining water quality, reducing flooding, etc. Local governments gain a clearer understanding of where these processes and functions occur in order to steer development to more appropriate areas and thereby reduce impacts to the processes and functions.

Plans and regulations based on scientific information may result in a more efficient permitting process by reducing the need to complete complex environmental review and detailed studies at the permitting level. They also can facilitate cooperation between jurisdictions, thereby further reducing cumulative impacts.

Minimizing the cumulative impacts of land use through landscape-based plans, policies, and implementing regulations can prevent costly problems by maintaining landscape processes and wetland functions over time. The result is a fiscally responsible approach to sustaining development.

6.4 Smart Growth

Smart Growth is a relatively new, conceptual framework for improving land-use planning and the management of growth in communities. It provides core defining principles intended to guide the development of land-use plans and policies as well as implementing regulations and practices. Its purpose is to minimize the negative effects of sprawl development on both local communities and the environment. Smart Growth integrates better economic, social, financial, and environmental outcomes for a community. It represents planned actions taken with all the community's benefits in mind both in the near term and well into the future.

Applying the principles of Smart Growth has been found to be fiscally beneficial by recognizing that certain patterns of growth and decline significantly hurt communities by undermining both their economies and the environment (Muro and Puentes 2004). In their paper *Investing in a Better Future: A Review of the Fiscal and Competitive Advantages of Smarter Growth Development Patterns*, Muro and Puentes (2004) found that Smart Growth can reduce public costs of installing new infrastructure and delivering new services, improve a region's economic performance, and bring economic gains to suburbs as well as cities. (See Appendix 6-A for additional references and web pages about Smart Growth.)

The National Governors' Association promotes the use of Smart Growth land-use planning and practices as beneficial for local communities. They recognize that it is not necessarily growth that is the problem but the patterns of sprawl-induced growth which are harmful (see the National Governors' Association web site www.nga.org).

Smart Growth focuses on growth that protects open space, revitalizes neighborhoods, and makes housing more affordable while improving the quality of life in communities. Fundamental to the Smart Growth concept are the following defining principles:

- Preserving and restoring critical environmental areas and the functions and services that these areas provide
- Strengthening and directing development toward existing communities
- Fostering attractive communities with a strong sense of place
- Reintegrating compatible uses in neighborhoods (mixed land use)
- Taking advantage of compact building design
- Creating walkable neighborhoods
- Providing a variety of transportation choices

When applying the concept of Smart Growth, local governments analyze the landscape using the best resource information available about the geographic area, identify the needs and desires of the citizens in visioning their community's future, and then evaluate different scenarios to accommodate future growth in a sustainable manner.

Landscape analysis is an important element of Smart Growth planning. However, it is only in recent years, since the advancement of the Geographic Information System (GIS), that conducting landscape analysis has been possible. Even more recent has been the development of methods to analyze landscape data which provide a scientific understanding of the sensitivities and stressors on natural resources and landscape processes. With this science-based knowledge, local governments and communities can, for the first time, improve their decisions about land uses and more effectively incorporate Smart Growth concepts into land management.

The concept of Smart Growth and its guiding principles can be applied through a variety of mechanisms. Land-use policies using Smart Growth principles encourage mixed-use zoning, limited outward expansion, higher density development, reduced travel, revitalization of urban centers, and preservation and restoration of open space essential to maintaining critical areas and landscape processes. Examples of planning tools using Smart Growth principles include Green Infrastructure planning and Alternative Futures analysis. Both are discussed later in this chapter.

Regulatory practices applying the Smart Growth concept focus on reduction of impervious surfaces, maintenance of tree and vegetative cover, compact building design, etc. Low impact development (LID), traditionally applied as a technical approach to

reducing stormwater impacts from developed lands, conceptually falls within the parameters of Smart Growth principles as well. Non-regulatory programs adopted using Smart Growth approaches emphasize preserving and restoring core greenspace areas. Preserving and restoring these areas is most effective when non-regulatory and regulatory tools are both applied.

Smart Growth planning offers the opportunity to take a proactive and resource-based approach to minimizing cumulative impacts on the landscape while maximizing environmental processes that benefit the community. At its best, Smart Growth has the potential to help direct future growth in ways that maintain or improve landscape processes and promote a healthy, functioning environment.

Washington's GMA incorporates some Smart Growth considerations in the directives for the use of critical areas ordinances, concentrating urban development and infrastructure, and conserving resource lands for long-term use. Many of the other Smart Growth elements that are planning and implementation tools can certainly be applied within the GMA context to bring the best land management practices to Washington.

6.4.1 Smart Growth Can Be Used to Develop or Update Local Plans

Smart Growth concepts and associated planning approaches can be applied at any time in the local planning process. (See Sections 6.4.2, 6.4.3, and 6.4.4 for a discussion of planning approaches which use Smart Growth concepts.) It is optimal to incorporate landscape analysis and Smart Growth concepts early in the process whenever a local jurisdiction intends to update its comprehensive plan and implementing ordinances, develop new subarea plans, or expand urban growth areas.

Updates to comprehensive and subarea plans are particularly important times for re-assessing the conditions of local landscapes and evaluating different development options for minimizing future impacts on ecosystems and landscape processes. Smart Growth approaches are more likely to succeed when they are discussed, developed, and implemented as part of a formal planning process. *Watershed academies* or *councils* (committees of scientifically informed citizens) can help guide the planning process. They can make recommendations on how to incorporate information about the landscape and principles of Smart Growth into land-use planning.

In areas close to urban centers that are not yet developed, into which urban growth boundaries may be extended, there is still an opportunity to tailor management needs within the landscape context. In more rural areas, harmful losses can be prevented by re-directing development to the least sensitive locations. These opportunities may well reflect the "best case" scenarios for balancing community needs while maximizing resource protection prior to development, thus sustaining landscape processes and natural resources to avoid expensive land-use problems in the future.

Smart Growth, and other planning processes that incorporate landscape analysis, can help define and identify specific restoration, preservation, and conservation needs and develop plans to address those needs. While it is unrealistic to think that an already built environment will be "un-built," mitigating or compensating actions (e.g., using restoration and preservation) might be identified and take place elsewhere in the vicinity to recover lost functions deemed beneficial by communities and resource managers. In this respect, some of the approaches described in this chapter, and elsewhere in Volume 2, can help identify and address restoration, preservation, and conservation needs in terms of landscape processes and target the type of implementing action needed for each site. (See Chapter 9 for more discussion of non-regulatory tools.)

A case study of the benefits of Smart Growth

A recent study by Preuss and Vemuri (2004) projected the effectiveness of Smart Growth practices implemented in Montgomery County, Maryland, in the 1960s. At that time Montgomery County implemented tools incorporating Smart Growth principles including transfer of development rights, cluster development, and open space acquisition through their land-use plans.

Preuss and Vemuri applied a dynamic model to predict the implications of using Smart Growth tools in Montgomery County during the last four decades. They did so by reviewing three different scenarios: 1) traditional policies, 2) current Smart Growth, and 3) full development. They found that Montgomery's current Smart Growth practices reduced negative effects on water quality and preserved more open space than the other two scenarios. In addition, under Montgomery's existing Smart Growth practices, developable land would still remain into 2050 while being non-existent under the other scenarios.

6.4.2 Planning Approaches Using Smart Growth

To illustrate the application of Smart Growth principles to planning, two approaches are discussed in the following sections: Green Infrastructure (Section 6.4.3) and Alternative Futures (Section 6.4.4). Both of these very similar, yet complementary, approaches examine how the services and infrastructure provided by natural resources can be used to benefit communities while maintaining those resources into the future. These planning approaches can readily be used by local governments to help develop comprehensive plan elements and help guide implementation of regulatory and non-regulatory programs. Comprehensive plans are discussed in Chapter 7.

By developing plans using Green Infrastructure or Alternative Futures, a local jurisdiction can develop the best *greenprint* or preferred alternative for the future. (See Section 6.4.3.1 for a discussion of the approach to developing a Green Infrastructure plan.) The conceptual land-use plan, often presented in the form of a map or maps, includes the location and type of all essential (core) areas that need conservation, preservation, and/or restoration (including degraded areas that provide opportunities to restore processes and functions).

These approaches can include both an assessment of the current and projected needs for infrastructure (e.g., transportation corridors and water and sewage treatment options) as well as the desired land-use patterns that will maintain and protect important environmental processes and functions. The implementation tools used to conserve, preserve, and restore the identified areas may be either regulatory or non-regulatory. Which protection measures work best at any location are determined by the functional attributes of the landscape, the overall risk associated with loss of the resources identified, and, ultimately, the community's vision of the landscape for the future.

See Chapter 8 for a description of restoration and preservation used in a regulatory context and Chapter 9 for restoration, preservation and conservation used in relation to non-regulatory activities. These terms are also defined in the glossary.

6.4.3 Green Infrastructure Planning

Green Infrastructure or *GRIST* is defined as an interconnected network of protected land and water that includes a wide variety of both relatively undisturbed and restored ecosystems and landscape features that make up a system of hubs and links. The network supports native habitat and communities, maintains landscape processes, sustains air and water resources, and contributes to the physical and economic health and quality of life of communities. In addition, this network of lands provides corridors for wildlife movement. (See Section 6.4.3.3 for conceptual illustrations of "hubs and links" and a simplified overview of the typical steps in developing and implementing a GRIST plan.)

The resulting network of ecologically important lands integrates:

- Waterways, wetlands, forests, wildlife habitats, and other such features
- Greenways, parks, and recreation lands
- Working farms, ranches, and forests
- Wilderness and other open spaces that support native species and maintain landscape processes

GRIST plans are an important element of Smart Growth because they help local planners identify and prioritize resources to be preserved, ensure the economic viability of working landscapes, and guide development in a manner that is compatible with sustaining landscape processes and the character of the community. GRIST plans provide a greenprint for accommodating land-use patterns while preserving critical areas, ecosystems, resources, and areas with native species and cultural assets. By integrating the benefits of landscape processes and services, GRIST plans assess current conditions and guide future land uses similar to how a transportation plan provides a blueprint for existing and future travel needs.

The President's Council on Sustainable Development identified Green Infrastructure as a key strategy for achieving sustainability in the report *Towards a Sustainable America – Advancing Prosperity, Opportunity and a Healthy Environment for the 21st Century* (Williamson 2003). Additional references on Green Infrastructure and Smart Growth topics are provided in Appendix 6-A.

6.4.3.1 The GRIST Approach

When developing a GRIST plan (or greenprint), conservation of landscape processes and critical areas establishes the foundation on which the rest of the local comprehensive plan is built.

Integrating the results of landscape analysis (as described in Chapter 5) into the GRIST plan ensures that the functions and processes necessary to maintain long-term protection of natural resources including wetlands are thoroughly understood and considered in avoiding future impacts or loss. For example, areas where significant groundwater discharge/recharge and storage occur would not be appropriate to zone for uses that would result in a high percent of impervious surfaces (e.g., roofs, driveways, roadways, and parking lots). These areas would be more appropriately zoned as open space or other low-density uses, rather than being designated for high-density development. The local jurisdiction might want to consider preserving such areas from development altogether so that the community's water supply is assured into the future.

A GRIST plan can also identify areas that provide important landscape processes that need restoration. For example, this might include areas where construction of levees has separated rivers from their floodplains or where drainage channels are conveying subsurface waters away from wetlands.

Thus, integrating the results of landscape analysis allows a jurisdiction to direct human activities to locations that avoid or minimize impacts to critical areas and other natural resources, sustaining them over time while supporting the community's needs for adequate water supplies, water quality, flood attenuation, etc. In addition, GRIST planning tracks the pace and location of land use in relationship to these outcomes.

GRIST plans are not open space plans

Traditional Open Space Plans (OSP) have been used by jurisdictions throughout Washington for years. These plans are usually developed by the local parks and recreation departments with the intent of securing open spaces which can provide the citizenry with recreation opportunities and/or scenic amenities.

GRIST plans, or greenprints, take the OSP concept further by also examining the functions provided by undeveloped lands and assuring continuity and connectivity between protected features. As the name implies, GRIST plans are designed to protect the "green infrastructure" on the landscape that provides for such "free" functions as flood attenuation, groundwater recharge, water quality filtration, etc. These functions, if lost, would need to be replaced by "engineered infrastructure," if they can be replaced at all. Additionally, conservation of habitat and biodiversity are also critical aspects of greenprints which are addressed by maintaining core areas with linkages (hubs and links) on the landscape.

Greenprints can be viewed as vital components for achieving both a healthy environment and sustainable communities. As such, they are the building blocks for implementing regulatory and non-regulatory programs. Thus, greenprints represent a community commitment to avoid costly environmental problems through proactive measures. For example, funds traditionally used for engineered infrastructure can be committed to implementing the plan when the functions of "green infrastructure" replace the need for built solutions.

Note: Some local greenprints still primarily focus on recreational lands only. These plans do not incorporate all of the broader principles of GRIST planning. Therefore, any reference to GRIST plans or greenprints in this document is referring to the broader description provided here and not plans that focus strictly on recreation.

GRIST Works in Both Undeveloped and Developed Areas

Communities at any stage of planning or development can incorporate Green Infrastructure into their planning processes:

- **GRIST planning for areas with little urban development.** When applying the results of a landscape analysis through a GRIST plan for a jurisdiction (or portion thereof) that has experienced little human development, a network of critical areas and resource lands can be identified for conservation. This network can be coordinated with plans for the built infrastructure such as essential transportation corridors. Essential "green infrastructure" can be preserved and/or restored while transportation corridors and built environments are accommodated. This clearly identifies where both public and private development will be better suited, thereby allowing land uses that are compatible with maintaining the integrity of the landscape and its processes.

- **GRIST planning for areas that are largely developed.** In jurisdictions where the landscapes have already been largely developed, applying the results of a landscape analysis through a GRIST plan can designate and protect remaining natural resources and critical linkages while still considering the existing roads, urban centers, etc. Here the results of a landscape analysis may provide its greatest benefit by identifying those portions of the landscape where essential processes and functions can and need to be restored to fill in the gaps where functions are needed.

6.4.3.2 Implementing a GRIST Plan

Implementing GRIST planning begins with incorporating the GRIST plan into the Land Use Element of the comprehensive plan (as well as the Shoreline Master Program). Other relevant elements of comprehensive plans should include policies and directives for successfully implementing the GRIST plan. In line with these policies and directives, regulatory and non-regulatory programs and tools should also be updated or developed.

The specific programs and tools to be used for implementation, and where and how they are applied, will depend on the goals and needs of the GRIST plan in relation to landscape processes, their level of degradation, their sensitivity to disturbance, and development pressures. For example, in a particular sub-basin it might be most critical to protect and maintain wetlands because the quality of the water is threatened by non-point pollution. Thus, policies for that basin may direct agricultural landowners to provide stronger buffer protections around aquatic resources. They may also encourage active restoration of aquatic habitats and their buffers, while zoning designations could reflect more stringent wetland standards to protect their ability to improve water quality. In an undeveloped area that provides aquifer recharge, policies and regulations may recommend low-impact development practices or even land acquisition as the preferred tool for protection.

6.4.3.3 Typical Steps for a GRIST Plan

While each local jurisdiction might need to develop a GRIST plan in its own way, there are some key steps that each should address (discussed below). Some of these steps may overlap with the landscape analysis discussed in Chapter 5. For detailed guidance on GRIST planning, please refer to the four-volume workbook titled *Local Greenprinting for Growth* (Trust for Public Lands and National Association of County Officials 2002).

Step 1- Develop the Overall Approach and Define the Geographic Scope

Developing a GRIST plan requires 1) defining the scope of the project, 2) establishing a means of engaging the community through education and public input and providing a forum for group decisions on the plan, and 3) understanding fiscal costs and benefits.

Decisions will be needed regarding the geographic scope of the GRIST plan and the resources that will be examined. The geographic scope is the portion of the landscape under consideration: Is it at the scale of the contributing landscape involving several

jurisdictions, or is it a management area such as a county, city, or sub-basin? Defining what areas should be part of a greenprint should ideally be examined in light of the sensitivity of different areas identified during the landscape analysis.

The community must be informed and engaged early in the process because GRIST planning is a process of community visioning and decision-making. Public understanding and involvement are essential to the success of the greenprint design. A communication plan should be created early in the process, identifying how the local citizens will be engaged, what committees will be used to make planning decisions, what will be their composition and decision-making power, etc.

It is advantageous to clearly articulate the fiscal savings that accrue as a result of GRIST planning from the start, both to the citizenry and government decision-makers. Some local jurisdictions conduct fiscal analyses comparing the cost of building infrastructure to the cost of protecting green infrastructure, including the tax savings that green infrastructure can provide to communities. Other fiscal benefits worth considering are those that result from attractive landscapes (e.g., parks and recreation lands, greenbelts, working farms, etc.). These greenspaces are increasingly important in attracting the creative workforce that can add to the economic growth of communities (Florida 2002). As mentioned previously, this is important information since the fiscal value of open space should be communicated to policy-makers as well as the community. (See Section 6.5 of this chapter for further discussion of fiscal benefits.)

Step 2 - Inventory Resources

Conducting an inventory of resources might consist of a landscape analysis as discussed in Chapter 5 or another method that is appropriate to assess the characteristics of the green infrastructure in the planning area. As discussed earlier in this chapter, using a landscape analysis ensures an understanding of the relationship of landscape processes and wetland functions (as well as other natural resources) and how they have been altered. Landscape data can be used in conjunction with information such as detailed ownership patterns and current or projected zoning overlays. Together, this information can assist with deciding how landscape processes and the functions provided by natural resources should be protected, as well as the type and location of preservation and restoration measures needed.

Figure 6-2 provides a simple, conceptual illustration of a landscape that has been inventoried as part of developing a GRIST plan. This graphic serves as the base for Figures 6-3 and 6-4 which illustrate subsequent steps in GRIST planning.

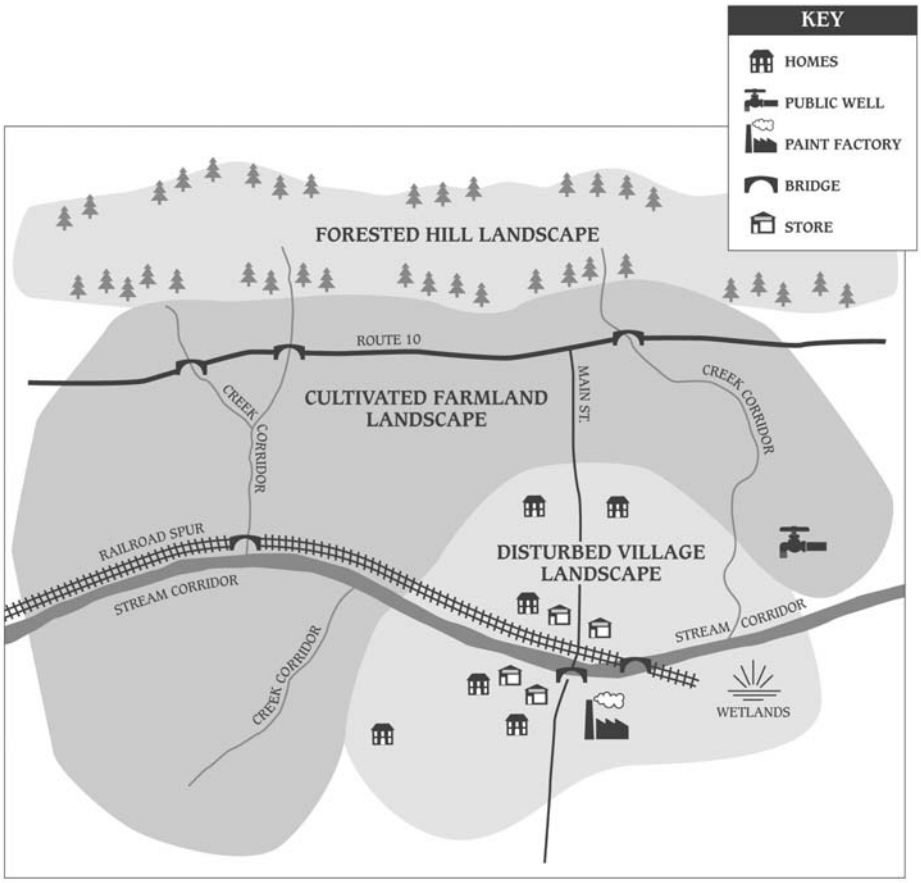

Figure 6-2. Conceptual representation of a landscape that has been inventoried as part of creating a GRIST plan (Figure provided by Heritage Conservancy, a non-profit land trust based in Doylestown, PA).

Step 3 - Envision the Future

Envisioning the future is when the community establishes overriding principles that guide the development of the GRIST plan. These are the goals for the greenprint and may include preserving critical areas and natural resources within each landscape type, maintaining and/or restoring landscape processes, providing or enhancing open space corridors, and so on. The visioning process also inherently should include discussion and identification of the least sensitive lands that are most appropriate for development for a range of uses that are prioritized by the community.

Step 4 - Finding the Hubs and Links

Finding the hubs and links requires a detailed examination of key ownership and land use patterns and defining how they will be addressed in the GRIST plan. Applying a landscape analysis helps to target those areas needing special protection because of their sensitivity or importance. From the landscape analysis, identification of existing or potential hubs and links will become more readily apparent. For example, cultivated lands, areas covered by forest, and existing preserves will be obvious "hub" points from

which to consider retaining or recreating "links" between the "hub" sites (see conceptual illustration in Figure 6-3). As this network is envisioned, steps needed to round out as well as implement the plan (e.g., purchasing parcels of land to connect habitat areas or restoring wetlands or riparian areas) become apparent.

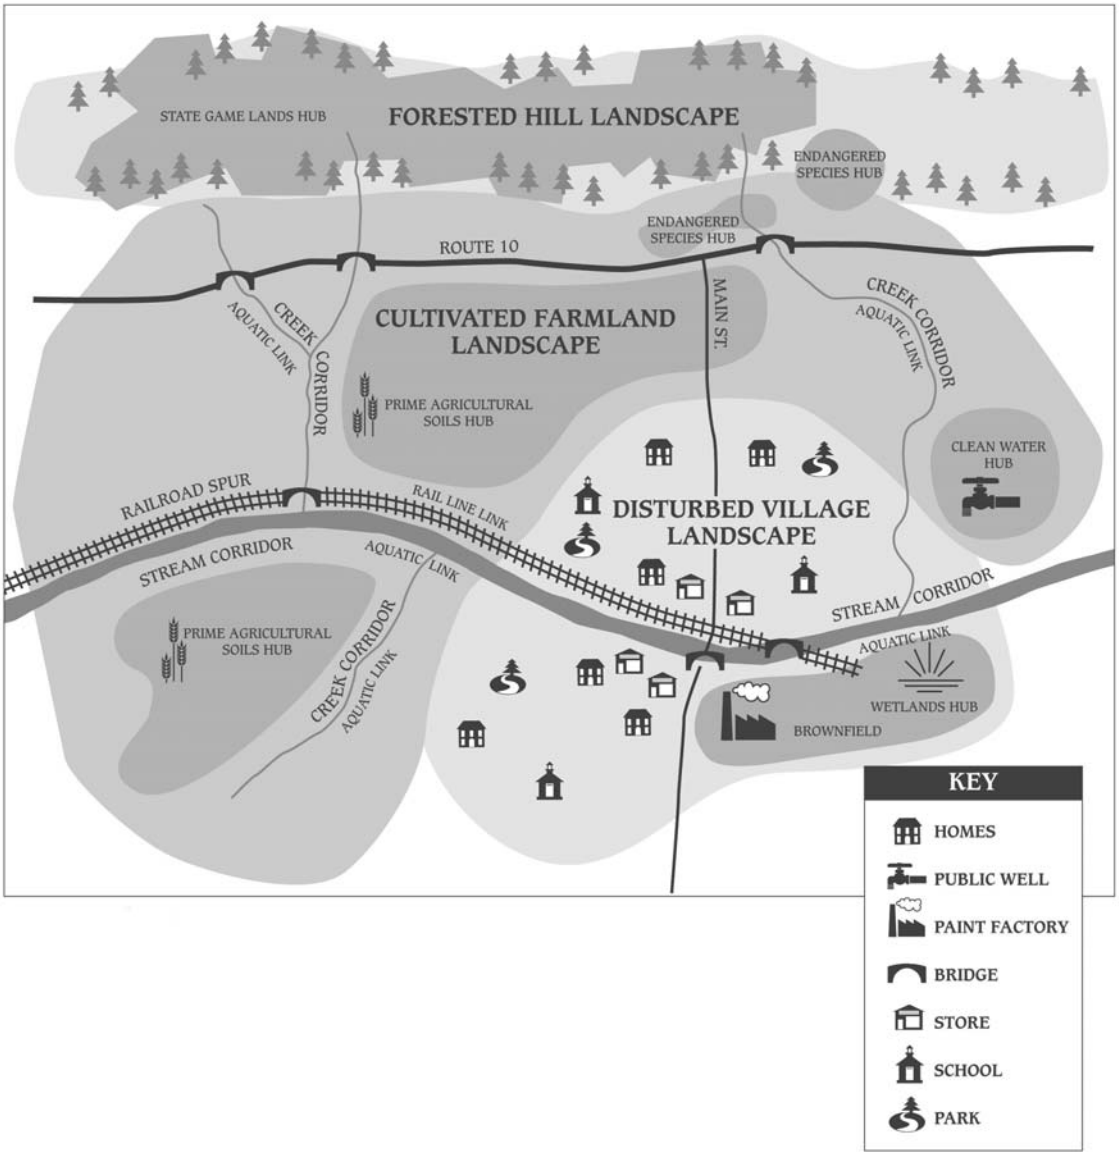

Figure 6-3. Conceptual representation of how hubs and links are identified as part of creating a GRIST plan (Figure provided by Heritage Conservancy, a non-profit land trust based in Doylestown, PA).

Step 5 - Creating the GRIST Plan

Creating the GRIST plan involves identifying potential land-use scenarios based on the information described in the previous steps. Alternative scenarios can be examined using

maps to apply different policy and zoning options. The community's goals for the future are applied to these options, and the appropriate course of action can be identified.

This stage in GRIST planning focuses on what specific provisions should be applied in various portions of the landscape to effectively conserve, preserve, and/or restore core areas of concern. At this stage of the process, the need to develop or revise the comprehensive plan, implementing policies and regulations, and non-regulatory tools should be apparent. Figure 6-4 provides a conceptual illustration of a completed GRIST plan.

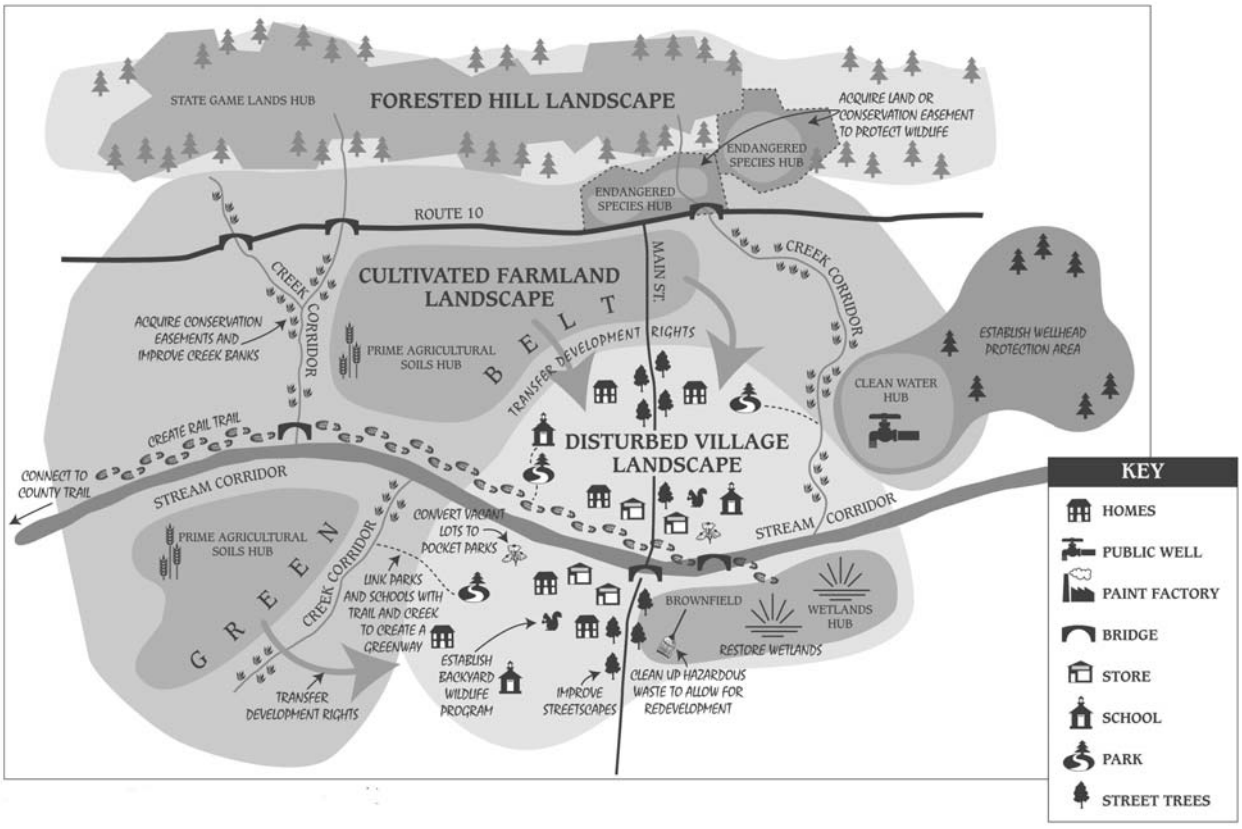

Figure 6-4. Conceptual representation of a completed GRIST plan (Figure provided by Heritage Conservancy, a non-profit land trust based in Doylestown, PA).

Step 6 - Implementing the GRIST Plan

Several means can be used to implement a GRIST plan, beginning with revisions to the Land Use Element of the comprehensive plan. From there, zoning designations and critical areas ordinances or other regulations can be modified as needed. In addition, non-regulatory programs can be established which contain a mix of landowner incentives, acquisition funding, and restoration components. The GRIST plan should be applied throughout the planning area as new zoning decisions and new regulatory protections are developed in proposed urban growth areas, master-planned communities, etc.

6.4.4 Alternative Futures

Alternative Futures is another approach to land-use planning that uses Smart Growth principles. It is similar to Green Infrastructure planning; however, the analysis phase is especially well developed to scientifically quantify the impacts to ecosystems from different, future development scenarios. (See Section 6.4.4.1 on determining the scope of the analysis for more discussion on the topic.)

Alternative Futures offers an excellent example of how a scientific examination of the landscape, when combined with community involvement, leads to a more informed planning process that results in improved environmental conditions and community vitality. As with Green Infrastructure, the community helps to make the informed decisions about land use when evaluating the different scenarios for future development.

A landscape analysis is used to create a series of scientifically supported scenarios that depict what the landscape might look like and how it will perform under different future land-use options. Each scenario is analyzed in regard to the environmental concerns and community priorities that have been identified, similar to those already discussed in the sections on Smart Growth and Green Infrastructure. The analysis uses metric measures (discussed later in this section) to play out the future depictions of development, allowing communities to better assess and evaluate the potential benefits and impacts of each scenario on the environment and community's quality of life.

As with Green Infrastructure, Alternative Futures relies heavily on involving an interested and informed citizenry in the planning and design of a desired future. A strong emphasis is placed on early communication, education, and participation. Community meetings are held to provide the public with maps showing examples of how the landscape will look under the different scenarios. Maps are used to compare different scenarios which reflect various policy and regulatory choices (ranging from more to less stringent protections). The sensitivity of the landscape to disturbances that would result from each scenario is evaluated carefully. Visually comparing the impacts of these scenarios provides an exceptional tool for helping the public to better understand what is at stake and thus make more informed land-use choices about their community's future.

When the preferred option is selected, the result is likely to be a land-use plan based on both protection of the environment and the identified needs of the community. As with Green Infrastructure planning, it is most likely to be both fiscally and environmentally sustainable. It represents the most informed choice, therefore, making it a "smarter growth" alternative.

6.4.4.1 Determining the Scope of the Analysis

The analysis, which is the hallmark of Alternative Futures, involves a broad, logic-driven process that incorporates the specific needs of a local community while evaluating land-use scenarios for their ability to retain long-term environmental and economic vitality. It begins with assessing the current condition of the landscape and land uses.

The community, with the technical assistance of supporting agencies, develops the scope of the analysis: size of the planning unit to be analyzed, scale of the effort, functions and issues that are of interest, the approach, method, and metrics used in the analysis, and the capabilities of the local government.

Size of the Planning Unit

The size of the landscape planning unit to be analyzed may be as large as a regional, terrestrial ecosystem (such as the Puget Lowlands), a large drainage basin (like the Snohomish River) or as small as a local sub-basin. The unit may cross several political boundaries or only encompass a limited portion of one jurisdiction. It may cover many miles and acres or only a few.

Scale of the Effort

The scale of the effort refers to whether the analysis will be designed to provide information for broader strategies and visions or for a more focused effort. This decision affects the type of scientific method(s) chosen and the level of detail that will be used to conduct the analysis. Generally, the analysis for broader strategies or visions involves larger geographic areas, and less detailed (more general) methods are appropriate. By contrast, a more focused planning effort might involve a sub-basin, for example, and require methods that result in more detailed information that is focused on spatially explicit, management options and recommendations. With this information, specific on-the-ground actions, or consequences, can be clearly evaluated.

Functions and Issues of Interest

Analyzing the landscape is the best approach to understand landscape processes and ecosystem functions at work across the planning unit and to examine ecological issues of concern. Therefore, the analysis may need to broadly cover a suite of functions and/or issues, or it may need to focus on specific areas of greatest concern. The community may decide the analysis should focus on current problems or problems that may result from future land uses. For example, the community may select flooding, water quality, habitat and biodiversity, or groundwater recharge as the issues/functions they believe should be examined in the analysis.

Approach, Method, and Metrics

Selecting the approach for conducting the Alternative Futures analysis will follow the previous decisions. Approaches that are "geospatial" must be compatible with the size of the planning unit, the scope of the process, and the scale of the effort. Geospatial refers to the geographic location and characteristics of natural or constructed features and boundaries on the Earth. Generally, geospatial approaches are used to simulate the effects of land-use change on landscape processes and ecosystems.

There are two geospatial approaches that can be used in an Alternative Futures analysis depending on the local community's particular needs:

- **Forecasting**. The common approach is to apply models that evaluate the impacts and environmental outcomes expected under several different development scenarios. Here each policy option is simulated in the model to predict the appearance and environmental performance of the future landscape, resulting from that policy choice.

- **Backcasting.** Alternatively, a concept called "backcasting" can be applied to develop future scenarios aimed at achieving certain desired end-points (Robertson 2003). In this approach, the future landscape condition is selected first. Then analysis and modeling are focused on effectively finding development policies that will successfully achieve that pre-chosen outcome. This is a very effective approach for holding the line in places where further degradation will collapse an entire ecosystem, leaving the community's economic vitality in crisis.

Method for Analyzing the Landscape

Before selecting the approach to use for an Alternative Futures analysis, a good starting point, as previously mentioned, is analyzing the landscape. Appendix 5-B lists some methods that can be used to analyze the landscape and one of the methods is being developed by the Department of Ecology (www.ecy.wa.gov/programs/sea/landscape). It provides a geomorphic examination of landscape processes in a defined area using a Geographic Information System (GIS). It is designed to be used in planning and can provide information at more than one geographic scale. For example, it can be used for larger planning units to provide a broad understanding of the processes at work in the landscape and to identify regional issues of concern such as water quality problems. It can also be used within smaller areas of interest or concern to conduct more refined analyses.

Products of Ecology's method for landscape analysis include characterizations of past, current, and potential environmental conditions. The analysis can identify problem areas that are of concern and relate them to the existing landscape processes and the ecological functions in the area. Examples include beaches with shellfish beds that have been closed, areas with poor water quality, habitat areas that need to be restored, etc. The analysis can be used to develop proactive strategies to avoid future impacts of development.

Assessment Metrics

Along with the landscape analysis method, equally important in the Alternative Futures analysis is the use of appropriate assessment metrics or measures: environmental indicators of condition, stress, or response within an ecosystem that can be used in a predictive manner. Metrics are usually selected based on a significant statistical correlation with scientific data linking environmental stresses to a predictable environmental response (e.g., a correlation between impervious surface and the condition

of aquatic habitats). Assessment metrics are often calibrated to better reflect local conditions within the specific area in which they will be applied. Several metrics are typically used in order to ensure the reliability of the analysis. The selection and use of such assessment metrics is an important and key component of evaluating alternative land-use scenarios.

Current research in the Pacific Northwest, and Puget Sound specifically, is building our understanding of some of the key stresses that affect landscape processes throughout the region and within particular local areas. Local researchers (e.g., Alberti et al. 2003), using geospatial techniques, are investigating and developing various assessment metrics essential to retaining watershed condition such as amounts of impervious surfaces, road density, number of stream crossings, and riparian and floodplain connectivity. These measures are being offered to practitioners for pilot testing and application.

When using these metrics, communities can expect to identify, for example, what percentage of cover from relatively undisturbed vegetation is needed to prevent problems within watersheds. Another example is what percentage of connectivity between habitats will assure that existing habitats remain viable. This information is directly used in the comparison of different land-use scenarios, for choosing the preferred alternative, and for implementation of the preventative or corrective actions that follow.

Local Government Capacity

It is important to recognize that the scientific rigor of the analysis and the success of the planning process may be dependent on a number of local factors such as:

- Type, extent, and reliability of natural resource data currently available in the landscape planning area
- Skills of existing staff in regard to conducting an Alternative Futures analysis, especially GIS applications
- Adequate funding to employ the assistance of consultants if needed
- Time needed to complete the steps of the analysis and planning process
- Ability to engage the public and coordinate the effort

Given all these factors, how an Alternative Futures process is conducted (both analysis and planning) will vary widely between jurisdictions and planning units. The value of conducting an Alternative Futures analysis, however, remains. It can provide important information such as the longer-term environmental costs and benefits of various development scenarios, thereby pointing out possible solutions and misperceptions. The result may be the achievement of multiple goals: protecting valued natural resources, maintaining or improving community quality of life, retaining economic vitality, and saving tax dollars. (See Section 6.5 for a discussion of fiscal benefits.)

6.4.4.2 Local Example of Alternative Futures Planning

In January 2001, the Kitsap County Department of Natural Resources used the Alternative Futures process to examine different scenarios in the Chico Creek watershed. The Chico Creek watershed drains 16.3 square miles of land west of Dyes Inlet in Kitsap County. Their goal was to develop an amendment to the County's comprehensive plan for this subarea. Locally referred to as "Planning by Watershed," the pilot Alternative Futures project was funded by the U.S. Environmental Protection Agency under a grant to the Puget Sound Action Team. Information regarding the details of the project can be found at: www.psat.wa.gov/Programs/growth/LID_futures.htm.

The County found the Alternative Futures approach was a unifying process that resulted in the integration of land-use planning with other regional efforts such as watershed planning, salmon recovery, clean water plans, as well as regulatory directives in the Growth Management Act. Using the Alternative Futures process, the county developed their preferred development scenario by:

- Conducting a technical analysis of current conditions in the watershed
- Involving citizens and interested parties in developing and selecting scenarios
- Testing the scenarios using Geographic Information System and scientific analyses
- Making an informed selection of the preferred scenario for future land use

To accomplish these tasks, they established goals for analysis of the watershed, analysis of the scenarios, and the planning process.

A strong component of Kitsap County's approach was public involvement. Five subcommittees were established, including an education work group, a public involvement work group, a technical work group, a restoration work group, and a watershed advisory committee. From these they constructed an effective education campaign and public involvement process.

Four scenarios were examined: 1) the "current regulatory" condition, 2) a "strong development" scenario, 3) a "strong conservation" scenario, and 4) a "moderate" scenario falling between development and conservation. A suite of analyses, using natural resource indicators, was conducted to identify the impacts of each alternative. The strong development scenario was quickly dropped due to the severity of impacts. The current regulatory condition then became the option with the greatest amount of development. In the end, the community selected the moderate development scenario which incorporated conservation-based patterns and practices.

Kitsap County officials were pleased with the benefits of the Chico Creek project and propose using the Alternative Futures process to develop subarea plans for other watersheds throughout the county.

6.4.5 Combining Complimentary Approaches

Landscape analysis, Green Infrastructure, and Alternative Futures are all complementary approaches. Applying the core elements of these three approaches in combination can offer a strong analytical package for making land-use decisions that will benefit communities while considering landscape processes.

Information about the landscape is an essential component of Green Infrastructure and especially Alternative Futures, as described in the preceding sections. In brief, it can be used as a tool to integrate information about different resources into the planning process in order to identify the issues of highest priority and develop alternative land-use scenarios. These scenarios can be analyzed (using GIS) and visually displayed as maps. Ecology's method for landscape analysis (www.ecy.wa.gov/programs/sea/landscape) can be used from a larger scale of analysis down to a smaller scale, thus assessing across scales and focusing in on key issues. Therefore, landscape analysis together with GRIST or Alternative Futures can provide a very useful complement for visually displaying and analyzing the effects of land-use decisions on the maintenance of landscape processes.

Adding the concepts of GRIST planning to Alternative Futures can:

- Reinforce the benefit of using landscape analysis as the basis for planning so that landscape processes can be sustained
- Emphasize the role of landscape processes and the functions of ecosystems such as wetlands as "infrastructure" and therefore worthy of protection for fiscal reasons
- Add hubs and links as corridors important to the maintenance of landscape processes
- Integrate working landscapes (such as agricultural and forest lands) as valued green space into land-use plans

The results of Alternative Futures may be more successfully implemented if combined with GRIST planning because it focuses on implementation using conservation measures and thus it can immediately advance conservation decisions which result from the Alternative Futures process.

Likewise, Alternative Futures compliments GRIST planning by:

- Applying metrics to quantify the impacts of disturbance on the landscape and to evaluate options
- Targeting sensitive features and critical functions which are important to include in a greenprint

6.5 Fiscal Savings and Other Benefits

Protection of landscape processes and the functions of ecosystems, such as wetlands and other critical areas, can provide important fiscal savings as well as other benefits. Many people assume that revenue will be lost as a result of land protection, while the costs of constructing infrastructure, to provide necessary services once green space is gone and landscape processes are degraded, are often overlooked.

Several recent papers have documented the costs associated with losing ecosystems that provide landscape processes and wetland functions. In *Taking its Toll: The Hidden Costs of Sprawl in Washington State*, Mazza and Fodor (2000) point to water quality and quantity impacts, smog and health issues, habitat and species losses, overall watershed decline, and general quality of life concerns. All of these losses can affect the economic viability of communities.

A report by the Trust for Public Land and The National Association of County Officials (2002) presents the numerous benefits of recognizing certain lands as necessities, not just amenities. The benefits include:

- Fiscal savings, which result when the benefits gained from preserving open space exceed the cost
- Economic benefits, when improved quality of life attracts business investment
- Free infrastructure, when green space provides services that avoid the expense of building infrastructure to replace functions, thus saving tax-payers' money
- Environmental benefits, when land-use planning is linked to the protection of landscape processes
- Health and social amenities, when, for example, recreation opportunities deter antisocial behavior by providing constructive activities, thereby contributing to the health and wellness of communities

The following paragraphs discuss and provide examples of three general types of fiscal savings resulting from protection of landscape processes through the planning processes described in this chapter.

6.5.1 Using Green Infrastructure Instead of Constructing Infrastructure

As demonstrated in the examples that follow, communities around the country that conduct a fiscal analysis of their revenues versus expenditures are finding that conservation of green infrastructure saves money in the long term. Purchasing and preserving land results in cost savings by avoiding the need to build infrastructure such as systems for controlling flood water when landscape processes and the functions of ecosytems are lost.

When New York City was faced with the need to spend $8 billion on new water filtration and treatment plants, they instead purchased 80,000 acres of land in the Catskill Mountains for $1.5 billion. The land functions to filter and purify drinking water. Purchasing the land (which is located in the watershed for the city) saved the city $6.5 billion by not building treatment plants and another $300 million a year in forgone costs of operating them.

In the Charles River Basin in Massachusetts, 8,500 acres of wetlands were acquired and preserved to provide storage for floodwater in the valley. The cost for acquisition was $10 million compared to the $100 million cost of an alternative proposal which would have resulted in the construction of dams and levees to accomplish the same goal (Fausold & Lilieholm, 1996).

The value of the tree canopy was illustrated in the Willamette/Lower Columbia region here in the Pacific Northwest. In a 7-million-acre area, the tree canopy has been reduced from 46% to 24% between 1972 and 2000 due to the expansion of roads, buildings, and pavement. This 28-year loss in canopy has resulted in $2.4 billion in costs for managing the increased stormwater runoff, according to a Regional Ecosystem Analysis by American Forests (2001). In addition, each year the lost canopy of trees would have absorbed 138 million pounds of pollutants and saved $322 million in related cleanup costs.

Despite the significant loss in tree canopy, the remaining forest continues to provide functions related to stormwater and water quality. According to the study, the region's remaining trees are still detaining and purifying a massive quantity of stormwater that would have otherwise required construction of a $20.2 billion treatment plant to manage runoff. The trees also absorb 178 million pounds of pollutants on an annual basis, whose potential cleanup would cost $419 million a year.

6.5.2 Increase in the Local Tax Base

Protecting areas that provide landscape processes can increase the tax base by attracting home buyers to properties near green spaces such as wetlands, thereby improving the homeowner's quality of life. This is called "enhancement value," the tendency of open space to enhance the property value of adjacent properties

Quality of life is a determining factor in real estate values and economic vitality. The green spaces of Portland, Oregon, for example, have helped build this city's reputation as one of the country's "most livable cities." A study in Portland found that residential property values increased, $436 for every $1000 feet, if they were in closer proximity to a wetland (Barclay et al. 2004). "The real estate market consistently demonstrates that many people are willing to pay a larger amount for property located close to parks and open space areas than for a home that does not offer this amenity," writes John L. Crompton, a professor at Texas A&M University (Sherer 2003).

The higher value of these homes means that their owners are paying higher property taxes, thereby benefiting the community as a whole. In some instances, the additional property taxes are sufficient to pay the annual charges on bonds used to finance the

acquisition and development of open spaces. This has been demonstrated in a study examining the proximity of residences to greenbelts in Boulder, Colorado. Here the average values of homes next to the greenbelt were 32% higher than those just 3,200 feet away. The study showed that the greenbelt added $5.4 million to the total property values of one neighborhood, generating $500,000 per year in additional property taxes. This was enough to cover the $1.5 million purchase price of the greenbelt in only 3 years (Sherer 2003).

Home owners can get tax relief to off-set an increase in property values and taxes if conservation easements are involved. Federal income tax law (U.S. Treasury Regulation Sec. 14 (h)(3)(i)) states that valuation of conservation easements is required to take into account the resulting increase in adjacent property value on land owned by the same donor.

The ability to attract business to a community is also affected by the presence of open space and the health of the environment. Barclay et al. (2004) have noted that environmental quality plays a pivotal role in the ability of a region to attract workers and new firms. They state that a community with a degraded environment is more likely to suffer economically.

It is important to note that the value of natural resources is not fixed in time: The values of many of the landscape processes and the functions of natural resources are growing as they become increasingly scarce.

6.5.3 Reducing Costs of Public Services

The cost of providing public services (roads, fire & police protection, etc.) to a community is less in areas with open spaces. A national study by the American Farmland Trust (cited in Mazza and Fodor 2000) showed that for every $1 generated in tax revenue, the median cost to provide services to residential areas was $1.15, while only $0.37 was spent in areas with agricultural or natural resource lands. The Trust conducted a similar study in Skagit County and found that infrastructure costs for residential services were $1.32 for each dollar of tax revenue as compared to $0.32 for farm, forest, and open space lands.

In addition, the tax base generated by new homes does not cover the actual cost of providing the basic services required. A study in Washington showed that the added expense of off-site facilities (such as schools) that would provide services to a typical new home is $20,000 to $30,000, which does not match the tax revenue generated to cover these costs (Mazza and Fodor 2000). Additional information on this topic can be found in a paper on the *Three Myths of Growth* (Fodor 1996), which debunks the belief that growth builds a tax base that provides enough revenues to cover the necessary services.

Developing land using the guidance of a GRIST plan may result in lower property and school taxes. For example, the town of Pittsford, New York, commissioned Behan Planning Associates to apply a fiscal model to determine the costs of expanded urban development versus the costs of land protection. The fiscal model predicted future tax

rates based upon the costs and revenues associated with future land-use patterns. The model estimated that, for the average tax payer, property and school taxes would increase only $1400 over 20 years using the "green infrastructure" scenario, in comparison to $5000 if the lands were fully developed under their existing policies. This analysis revealed that it would be much less expensive to implement the greenprint than allow development in the wrong locations (Trust for Public Land and National Association of County Officials 2002).

Additional resources

Many resources are available for local governments that wish to pursue Smart Growth, Green Infrastructure, Alternative Futures, and associated concepts discussed in this chapter. For further information, see the published and online resources listed in Appendix 6-A.

Chapter 7

Prescribing Solutions: Comprehensive Plans

7.1 Introduction

This chapter builds on the discussion in Chapter 6 about planning approaches that can be used to develop or update a comprehensive plan. The planning tools discussed in Chapter 6, such as Green Infrastructure and Alternative Futures, allow jurisdictions to use the data generated from a landscape analysis to create a vision of the future, integrating landscape-scale issues with the community's priorities regarding land uses.

Developing or updating a comprehensive plan, and the other planning approaches discussed in Chapter 6, are all part of Step 2 (Prescribing Solutions) in the four-step framework discussed in this volume (Figure 7-1). The tools for landscape analysis described in Step 1 (Chapter 5) can provide information to help guide the development or revision of a comprehensive plan, shoreline master program, or other planning effort. Regulatory and non-regulatory solutions, discussed later in Chapters 8 and 9, are also part of Step 2 and can be used to implement plans and policies.

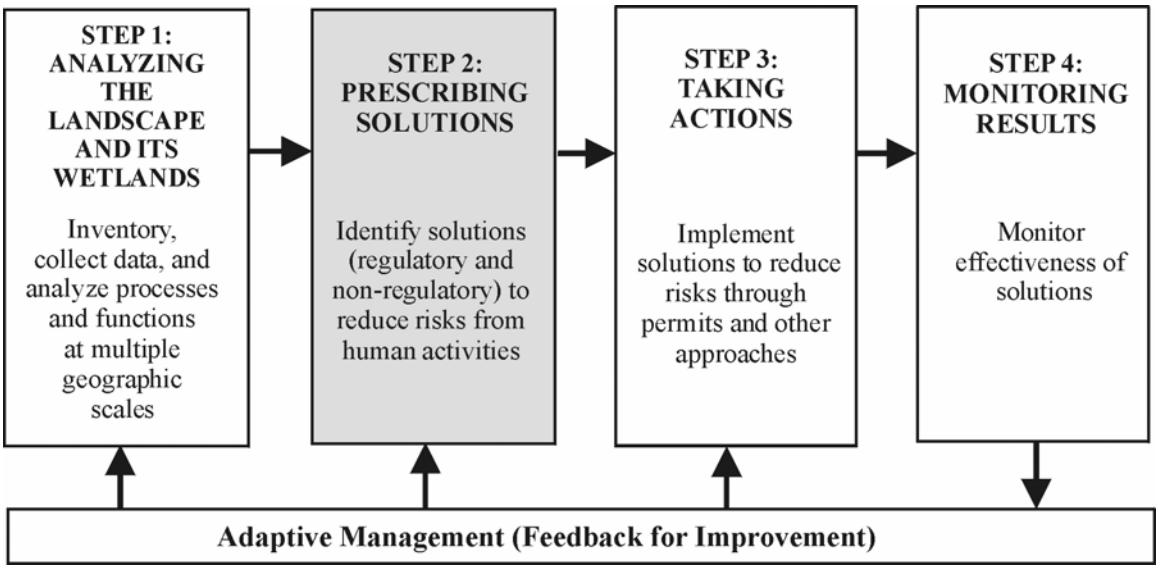

Figure 7-1. Comprehensive planning is part of Step 2 in the four-step framework recommended for protecting and managing wetlands (shaded box).

By integrating landscape analysis and public involvement into the planning process, effective policies and regulations can be developed that reflect choices about land use that will protect, maintain, and restore landscape processes. Therefore, the results of landscape analysis should be incorporated into the goals and policies of the relevant mandatory and/or optional elements included within comprehensive plans. Because comprehensive plan goals and policies establish the basis for much of the regulatory language and codes, such as zoning, developed by a jurisdiction, the information in a comprehensive plan should reflect what is needed to maintain landscape processes and protect wetland functions and values.

Doing a landscape analysis is not a recommendation to implement an entirely new process. Aspects of a landscape analysis, as described in this volume, are already a required part of developing or amending/updating a comprehensive plan. The reader is referred to Chapter 6 for a thorough discussion of the importance of using information generated by a landscape analysis to inform planning, including comprehensive planning.

Although it is important to use information that includes data from the scale of the contributing landscape, comprehensive planning is conducted at the scale of the management area. The management area is restricted to the lands over which a jurisdiction has authority, because the boundaries for planning are political, not driven by the environmental processes at a landscape scale. This chapter provides a brief overview of comprehensive planning (Section 7.2), followed by a discussion of the mandatory and optional elements, including subarea plans, of comprehensive plans as established by the Growth Management Act (GMA) (Sections 7.3 and 7.4). The chapter includes examples of how typical language in a comprehensive plan can be modified to incorporate landscape analysis. It also discusses how subarea plans can be used by jurisdictions that would like to incorporate landscape information within a smaller planning area.

7.2 An Overview of Comprehensive Planning

As discussed in detail in Chapter 2, and summarized briefly in the introduction of Chapter 6, the GMA dictates that counties and cities that meet certain provisions must plan for future growth (RCW 36.70A.040). They must develop comprehensive plans and development regulations, including critical areas ordinances, to meet the intent and requirements of the GMA (RCW 36.70A.020). Comprehensive plans and regulations are subject to continuing review and evaluation by the county or city that adopted them. The GMA also requires local jurisdictions to include best available science in the development of policies and development regulations used to protect the functions and values of critical areas, including wetlands (RCW 36.70A.172).

The key GMA requirements are as follows:

- Identify and protect critical areas and resource lands
- Designate county-wide planning policies and urban growth areas (for counties and cities fully planning under the GMA)
- Prepare and adopt comprehensive plans
- Adopt development regulations to implement the comprehensive plan
- Evaluate and update the comprehensive plan and development regulations

Comprehensive planning, as the name implies, is a planning process that encompasses all the activities that occur or may occur on the land over which a local government has jurisdiction. Typically, a comprehensive plan consists of a "map or maps and descriptive text covering objectives, principles and standards" used for its development (RCW 36.70A.070). A comprehensive plan is a document that provides direction for decisions about land use in a local jurisdiction. As described in the introduction to the Spokane County Comprehensive Plan (http://www.spokanecounty.org/BP/Documents/CompPlan/Chapter1.pdf):

> *The Comprehensive Plan is a set of goals, policies, maps, illustrations and implementation strategies that states how the County should grow physically, socially, and economically. The plan emphasizes innovative and flexible strategies to guide growth and development. One of the central themes of the Plan is the promotion of economic development that occurs in harmony with environmental protection and preservation of natural resources. The Plan recognizes the interests of the entire community and promotes cultural and ethnic diversity.*
>
> *The Comprehensive Plan establishes a pattern of land uses to shape the future in desirable ways...*

A comprehensive plan is composed of elements that address typical issues for a jurisdiction. Elements such as transportation and capital facilities (e.g., domestic water sources, sewage treatment, essential public facilities, and stormwater facilities) are incorporated into the planning process to ensure that adequate infrastructure is provided for existing and future land uses. In addition, there are elements that address the protection of natural resources, such as agricultural areas, and critical areas such as wetlands, geologic hazard zones, and fish and wildlife habitat.

Under the GMA, comprehensive plans must contain the following elements:

- Land Use Element
- Transportation Element
- Housing Element

- Capital Facilities Element
- Utilities Element
- Shorelines Element
- Rural Lands Element (for counties)

Also, if state funding is provided, Economic Development and Parks and Recreation Elements are required to be included in plans.

Optional elements may also be included in comprehensive plans, such as conservation, energy, recreation, and subarea plans, where appropriate. Some jurisdictions include additional elements that consider the environment. For example, Skagit County includes an Environment Element that specifically focuses on the influences of wetlands, streams, wildlife habitat, and other environmental factors on planning and land use, whereas Yakima County includes a Natural Setting Element. Overall, the plan "shall be internally consistent and all elements shall be consistent with the future lands use map" (RCW 36.70A.070) and shall be coordinated with the comprehensive plans of jurisdictions with common borders or related regional issues (RCW 36.70A.100).

The Legislature also set forth goals to guide the development of comprehensive plans. Application of a landscape analysis and principles for low impact development would assist in meeting the following of those goals:

- Encouraging development in existing urban areas
- Reducing sprawl
- Ensuring that adequate public facilities are in place for new development
- Retaining, enhancing, and conserving open space, recreation, and habitat areas
- Protecting the environment and enhancing water and air quality and availability of water
- Meeting the goals and policies of the Washington State Shoreline Management Act as set forth in RCW 90.58.020
- Encouraging economic development that is within the capacity of the state's existing natural resources

The Legislature also directed local governments to include innovative techniques for land-use management in their comprehensive plans, including density bonuses, cluster housing, planned unit developments, and transfer of development rights (RCW 36.70A.090). Landscape analysis and principles of low impact development would also assist local governments in meeting this provision.

7.2.1 County-wide Plans and Policies

The GMA establishes counties as the primary units for regional land-use planning. An important aspect of planning under the GMA is the requirement for counties to adopt planning policies that are county-wide under RCW 36.70A.210. County-wide planning policies are adopted in consultation with the municipalities in the county, to support and guide cross-jurisdictional cooperation between the county and the municipalities located within it.

At a minimum, a county-wide planning policy needs to address the development of urban growth areas, joint planning for these areas, siting public capital facilities of a county-wide or state-wide nature (such as transportation facilities), providing for affordable housing, economic development and employment, and analyzing the fiscal impact of the policies. The county-wide policies are binding on state agencies. Large urbanizing counties (those with population greater than 450,000 people) adjacent to each other are required to adopt multi-county planning policies.

Plans and policies for critical areas may need to be amended to create the basis of regulations that include best available science across jurisdictions. Because critical areas such as wetlands and the landscape processes that support them often span multiple jurisdictions, local governments should consider whether their current policies and regulations are consistent with the programs of neighboring jurisdictions. Jurisdictions should not, however, reduce regulatory protections for critical areas as the sole basis for achieving consistency across jurisdictions.

In fact, managing natural resources at the larger geographic scales of contributing landscapes or watersheds has become recognized internationally as an important approach to protecting aquatic resources, including wetlands (United Nations 1997). While planning at this scale may be beyond the purview of comprehensive planning for some local jurisdictions, it is possible for local jurisdictions to join existing programs to develop plans and actions at larger geographic scales. Examples of regional planning efforts being conducted by state and federal agencies related to aquatic resources are described in Appendix 7-A.

7.2.2 Tools for Implementing Comprehensive Plans

The policies of comprehensive plans can be implemented through a variety of means. The most common and effective approach is to include policies in development regulations adopted through ordinance that then become mandatory. In some jurisdictions, policy language can be implemented through provisions of the State Environmental Policy Act. However, policy language is often viewed as more discretionary than development regulations that are adopted.

Under the provisions of the GMA, development regulations have to be consistent with the comprehensive plan that the jurisdiction has adopted. This is one of the key provisions of the GMA related to comprehensive plans and regulations: Ensure consistency between

plans, policies, and regulations, and provide coordination between contiguous jurisdictions.

The policies, goals, and values identified in the comprehensive plan are implemented through these regulations. Regulations are adopted through ordinances to prescribe general and permanent rules. In conflicts concerning development activity, the development regulations are the primary means for resolving disputes and carry more legal weight than the comprehensive plan policies. Regulatory tools are discussed in Chapter 8.

A comprehensive plan can also be implemented through non-regulatory tools, as discussed in Chapter 9 of this document.

7.3 Mandatory Elements of Comprehensive Plans

Under the GMA, comprehensive plans must contain certain mandatory elements. Many of the mandatory elements of a comprehensive plan (RCW 36.70A.070) can incorporate the results of a landscape analysis and the Smart Growth planning processes described in Chapters 5 and 6. The mandatory elements that are the most applicable to wetlands protection and management include:

- Land Use Element
- Capital Facilities Plan Element
- Rural Lands Element (for counties)
- Transportation Element

Optional plan elements, especially conservation plans and subarea plans, may also be important in order to create an effective program to protect and manage natural resources that minimize cumulative impacts. These optional elements are discussed in greater detail in Section 7.4.

Each of the mandatory elements that can most appropriately be used for protecting and managing the landscape processes that maintain wetlands and their functions are described below. Examples of text for policies that incorporate landscape analysis are provided for each element.

7.3.1 Land Use Element

The Land Use Element is the heart of the comprehensive plan. It determines the "proposed general distribution and general location and extent of the uses of land" including population densities, building intensities, and future population growth estimates (RCW 36.70A.070).

The tone of the Land Use Element is set by the text of the Introduction and Framework, which identify key guiding values and the priorities of the community. For example, as noted in the opening paragraphs of the City of Cheney Land Use Element (http://cityofcheney.org/planning/comp_plan/comp_plan7.pdf):

> *The Land Use Element of Cheney's Comprehensive Plan is central to the entire planning process. The land use patterns are what determine the character of the community and dictate the types and locations of future development. This element of the plan determines the traffic patterns and the ability or inability to effectively alter those patterns over time. It can be sensitive or insensitive to the natural and physical characteristics existing within a community and, overall, it is the primary element which will determine the quality of life for the citizens of Cheney.*

In Skagit County, the Land Use Element focuses almost exclusively on human uses of the land in current and future conditions. The County's Land Use Element assesses the condition, location, and distribution of existing land uses and identifies the appropriate intensity and density of land uses for the future based on development trends in the county and surrounding areas. The Land Use Element includes guidance for the development of commercial and industrial land uses as well as residential, agricultural, and other uses.

In some comprehensive plans, the Land Use Element begins by describing in some detail the natural history and ecological conditions of the landscape within the jurisdiction. This information is then used to plan land use on the landscape. The City of Bainbridge Island, for example, uses this approach to establish a "sense of place" before designating land use types. Other comprehensive plans do not include an extensive natural history section, but limit their descriptions to the existing and proposed land uses within the jurisdiction.

The Land Use Element must specifically provide for the protection of groundwater that is used for potable water. Also, where applicable, the Land Use Element must review drainage, flooding, and stormwater runoff and provide guidance for corrective actions to mitigate or cleanse those discharges that pollute waters of the state.

Most comprehensive plans state one or more "goals" which are vision statements that attempt to identify the priorities and values of the community. Following the goals may be a series of one or more "policies" related specifically to each identified goal. Sometimes the policies overlap or are even repeated from one goal statement to the next or from one element of the comprehensive plan to another.

7.3.1.1 Incorporating Landscape Analysis into the Land Use Element

Logically, landscape data, or any environmental information, should be collected and analyzed prior to drafting the Land Use Element of the comprehensive plan. The analysis outlined in Chapter 5 identifies landscape processes as well as wetlands and their

functions. It identifies which areas need special management because they provide important processes, such as groundwater recharge and how wetlands function and contribute to the larger landscape processes. This type of analysis can also identify areas that, if restored or preserved, could improve functions and reduce cumulative impacts that cannot be avoided.

The Land Use Element can identify:

- The location and type/intensity of development consistent with protecting critical resources
- Areas critical to maintaining processes that support wetlands (e.g., infiltration and recharge areas, areas of critical subsurface and surface flow, discharge areas, areas of potentially high runoff)
- Areas that require restoration of landscape processes
- Areas that require protection (i.e., no development) in order to maintain critical landscape processes

The results of the landscape analysis described in Chapter 5 and additional planning approaches, such as Green Infrastructure or Alternative Futures analysis discussed in Chapter 6, can be used to guide the choices of land-use designations within a jurisdiction. Conducting a landscape analysis identifies critical locations within the management area where key landscape processes or wetland functions are provided. Integrating that information into a Green Infrastructure plan or an Alternatives Futures analysis allows the community to make informed decisions about land use that incorporate both human needs and environmental considerations at many geographic scales. The resulting land use choices, priorities, and goals can then be included in the policies of the Land Use Element. Such an approach can help ensure long-term maintenance of landscape processes and reduce the deficiencies of case-by-case permitting decisions.

7.3.1.2 Using Landscape Analysis in Different Sections of the Land Use Element

The policies in the Land Use Element provide the foundation for developing subsequent elements of the comprehensive plan, other plans, and regulations, and non-regulatory components of programs. The Land Use Element of a comprehensive plan may typically be divided into Overviews, Goals, and Policies. The shaded box on the next two pages provides an example of the Table of Contents of a typical Land Use Element (the example is modified from a draft of the City of Bainbridge Island's Land Use Element). The major sections of a Land Use Element are then discussed in detail following the shaded box. For specific portions of the Land Use Element, modifications are suggested regarding where to incorporate landscape analysis. Explanatory text and policies for the relevant portions and, in some cases, examples of text that could be used directly are provided.

Sample Table of Contents for a Land Use Element

Introduction

Framework of the Plan

Overview of Existing Conditions – Natural Environment

Note: This section describes the biological, physical, and geographic conditions of the jurisdiction. The same combination of data can be used in the landscape analysis (described in Chapter 5) to establish baseline conditions. The results of the landscape analysis would be woven through each of these sections, identifying the physical and biological linkages and areas that are critical for maintaining landscape processes and wetland functions.

Geography

Climate

Geologically Hazardous Areas

Watersheds

Wetlands

Streams

Groundwater

Aquifer Recharge Areas

Fish and Wildlife

Overview of Existing Conditions – Built Environment

Note: This section describes the human-made conditions and land uses currently present in the jurisdiction.

Residential Development

Commercial Development

Overview of Existing Conditions – Resource Lands

Note: This section describes the resources that humans use for economic purposes.

Agriculture

Forest Land

Mining

Goal and Policies/Principles of the Built Environment

Note: This section outlines the overriding intent and values of the jurisdiction for the built environment. Each subsection below contains the policies or principles that create the framework on which subsequent community plans and/or regulations are developed.

Framework of the Plan

General Land Use

Neighborhood Service Centers

Light Manufacturing

Residential Open Space

Environment

Sample Table of Contents for a Land Use Element (continued)

Goals and Policies/Principles of the Natural Environment

Note: This section outlines the intent and values of the jurisdiction for the natural environment.

- Fish and Wildlife Policies
- Aquatic Resources
- Frequently Flooded Areas
- Geologically Hazardous Areas
- Atmospheric Conditions
- Greenways

Goals and Policies/Principles of Natural Resource Lands

Note: This section outlines the intent and values of the jurisdiction for managed natural resource lands.

- Agricultural Lands
- Forest Lands
- Mining

The **Introduction** to the Land Use Element provides an overview of the Land Use Element and how information was obtained. If landscape analysis, or other environmental data, Green Infrastructure planning, or Alternative Futures analysis are incorporated, there should be a brief description of the methods used to generate the information.

The **Overview of Existing Conditions - Natural Environment** is where the results of a landscape analysis can be presented. It can also be where the criteria for establishing priorities for proposed land uses are described. The existing condition and the criteria for priorities set the stage for the future and would benefit from incorporating information about natural resources at all geographic scales. This would also be the location to describe the findings of Green Infrastructure planning or Alternative Futures analysis (discussed in Chapter 6), particularly in reference to establishing priorities. In this section it would be reasonable to present the conclusions from any public process used to create criteria or priorities for land use designations, as well as recommendations for preservation or restoration.

The **Overview of Existing Conditions - Built Environment** provides a summary of the relevant conditions of the developed lands within the jurisdiction. The character and extent of housing and lands zoned for various levels of residential use are described and contrasted with expected demands. Depending upon the jurisdiction, the section may contain descriptions of commercial and industrial lands, infrastructure (e.g., domestic water and public sanitary sewer systems), and transportation in sufficient detail on which to base the planning process. The overview of infrastructure and capital facilities is usually brief to illustrate existing conditions; detailed discussions are contained in the appropriate elements of the comprehensive plan. This section may include a description

and discussion of existing housing stock and residential zoning designations. If the results of a Green Infrastructure planning or Alternative Futures analysis include recommendations or criteria for housing considerations, this is the location for those findings.

The **Overview of Existing Conditions - Resource Lands** focuses on lands used for commodities: agricultural lands, commercial timberlands, and mining and mineral extraction. Depending upon the jurisdiction, the overview may or may not describe lands zoned for commercial resource use. The results of Green Infrastructure planning or Alternative Futures analysis may identify some of these lands as critical hubs or links from the perspective of maintaining or restoring landscape processes. It is appropriate to discuss those findings in this section.

The next sections of the Land Use Element present examples of policies for the Natural Environment, Built Environment, and Resource Lands. Polices are statements that guide more detailed planning documents conducted at a management scale, such as community plans, basin plans, or neighborhood plans, as well as Green Infrastructure or Alternative Futures plans. These policies also form the basis for a jurisdiction's regulations. The policies must reflect the priorities for the jurisdiction. The policies should reflect the findings of a landscape analysis (or any environmental analysis) and the priorities of the community.

7.3.1.3 Landscape Analysis in the Policy Language of the Land Use Element

Policies can be modified to reflect the need for analyzing and protecting landscape processes that are necessary for the long-term protection of wetlands and the functions they provide. Specifically, a statement in the Introduction or opening section of the Land Use Element can provide the foundation for subsequent policies and regulations.

A policy statement can be created that directs the jurisdiction to use landscape analysis to identify lands that are critical to maintaining landscape processes, then to use this information in determining land use designations. Example policy statements include:

- A landscape analysis shall be conducted for each [subarea/planning area/sub-basin] to identify lands that are critical for the maintenance or restoration of the landscape processes that maintain wetland functions and minimize cumulative impacts

- Green Infrastructure planning or an Alternative Futures analysis will be conducted within each [subarea/planning area/sub-basin] to establish criteria and set priorities for land-use designations and protection of the landscape processes that maintain wetland functions

Below are two examples of typical policy statements that have been modified to include landscape analysis (new language is shown in *italics* and deleted words are indicated by ~~strikethrough~~):

- ~~Identified~~ Critical areas, *critical habitats,* shorelands, aquatic resource areas and natural resource lands *identified through a landscape analysis* shall be protected by restricting conversion *or rezoning to a buildable designation*; encroachment by incompatible uses shall be prevented by maintenance of adequate buffering between conflicting uses *and habitat function shall be maintained by establishing connective linkages between critical habitats identified in the landscape analysis*

- Open space corridors within and between urban growth areas shall be identified *based on the landscape analysis of critical habitats and linkages*; these areas shall include lands useful for recreation, fish and wildlife habitat *including corridors for movement between habitats,* trails, and connection of critical areas *to essential habitats to avoid future fragmentation*

Many existing policies in typical planning documents already include language that suggests identification and protection of environmentally sensitive lands. Examples of policy language that could be used to revise the Land Use Element of a comprehensive plan follow. These are only examples; there are many ways that the intent of these examples can be incorporated into a Land Use Element.

General Land Use

General Land Use goals and policies provide more detailed guiding principles for overall land use within a jurisdiction. The general goals for land use listed below have been revised (new text is in *italics*) to show that little modification may be required to incorporate protection of landscape processes and wetland functions based on the results of landscape analysis.

- Support land-use development patterns which protect public, health, safety and welfare, *and the long-term protection of the environmental processes at all geographic scales that support the functions of critical areas, including wetlands*

- Encourage dedication of open space *that is identified as critical for maintaining environmental processes or for providing habitat linkages based on a landscape analysis,* preserve *existing upland forest to the extent feasible,* and encourage the restoration of trees and vegetation to maintain the feel of the community

- Guide future development into concentrated urban growth areas where adequate public facilities, utilities and services can be provided

- *Use appropriate development techniques to minimize impervious surface and maximize infiltration of surface runoff*

- Protect and conserve long-term, commercially viable forest, agricultural, and mineral natural resource lands

- Retain rural landscape features and lifestyles
- Maintain open space, recreation, fish and wildlife habitat, scenic and significant historic archeological cultural lands *by identifying, through a landscape analysis, the critical habitat areas and linkages across the landscape to ensure their protection*
- Enhance the community character, natural beauty, and environmental quality *by ensuring protection of critical areas and linkages through appropriate land-use designations*
- Help preserve rural economies
- Foster opportunities for rural-based employment, self-employment, and economic diversification
- Permit the operation of rural commercial businesses, natural resource related industries, recreation and tourism activities, cottage industries and small-scale businesses, and home occupations that are consistent with existing and planned land use patterns and are of an appropriate size and scale to maintain rural character

Residential Open Space

The Residential Open Space section can be the location for a goal that creates flexibility in lot configurations or density through such mechanisms as transfer of development rights (TDR), discussed in Chapter 9. The following are examples from typical policies for Residential Open Space that have been modified (in *italics* or ~~strikethrough~~) to incorporate landscape analysis:

- Protect open space, *assure the long-term protection of* critical areas *and the environmental processes that sustain them at all geographic scales*, and *assure sustainable* agricultural uses through public and private initiatives, including open space tax incentives, cluster development, planned unit development (PUD), transfer and purchase of development rights, public land acquisition, greenways, conservation easements, landowner compacts, down-zoning, limiting the amount of lot coverage, and other techniques
- *Encourage preservation of key habitat linkages between critical areas, allow* the aggregation of nonconforming lots of record and undeveloped subdivisions and short plats, so as to achieve ~~consistent with goals of the Plan~~, a development pattern that provides affordable housing, preserves open space, protects *critical areas and landscape linkages*, and protects water resources
- *Establish and maintain* vegetated buffers *around critical areas* to preserve the community's rural character *and maintain upland habitat adjacent to aquatic resources; to assure the presence of forest buffers over the long term, require the*

planting of native conifer seedlings within the margins of forested buffers left when adjacent upland forest is cleared for the creation of lot

- New development should be responsive to the natural landscape conditions and should *reflect the results of a landscape analysis* so as to have the least environmental impact on the community's landscape

- *Forested steep slopes,* particularly ridge lines, shall be protected for their visual, aesthetic, *and habitat-linkage* benefits, *including* their functions as wildlife habitat, and *for control of* erosion and *sedimentation*

- A Flexible Lot Design Subdivision process will be created to encourage more creative development *that has the flexibility to reflect site conditions including the results of a landscape analysis.* Flexible lot design *can* integrate use of open space and placement of buildings and infrastructure to reflect site conditions. It will include a cluster zoning requirement in the subdivision process and ensures that the approval process is timely and efficient. The following criteria shall be considered for flexible lot design:

  – Suitable soils for individual, on-site septic systems *or the presence of a community treatment facility*

  – *The findings from the landscape analysis to identify key habitats, and appropriate habitat linkages across the landscape; flexible lot design shall incorporate a perimeter buffer to the development which also provides visual screening of the site from public roadways, and maintains public viewsheds*

  – *Where feasible, grading should be minimized and trees should be maintained as much as possible throughout the project area*

  – Land that is designated as permanent open spaces within Flexible Lot Design Subdivisions shall be used either for recreational, conservation, or *ongoing* agricultural uses; *lands designated for conservation shall not be used for active recreation or initiating agricultural uses;* recreation or agricultural lands shall *be* dedicated to the community, or to a private, non-profit organization

  – Revise the PUD section of the zoning ordinance to provide greater flexibility in design and provide density bonuses for imaginative design, preservation *of identified* environmentally sensitive areas *including aquifer recharge, floodplain, critical wetlands and habitat linkages identified through a landscape analysis*, and include a broad range of housing alternatives

Environment

Within the Environment Element, a variety of goals and policies can be established to implement the intent of the guiding policies. For example, the following three goals are stated in the opening text of the Environment Element of the City of Olympia comprehensive plan (http://www.trpc.org/resources/olycompplan03_ch2_environment.pdf):

- *Long-term economic progress and environmental protection are mutually dependent*

- *Future generations have a right to an environment which has greater environmental assets than today*

- *A healthy environment contributes to the economy no less than do roads and other public services*

Examples of typical Environment policies that have been modified (new text in *italics*) to include recommendations from this volume are:

- Whenever there is *a proposed rezoning* or subdivision of land, the community *shall use the information from a landscape analysis to help assess and* consider the impact of the proposed project on critical areas

- *Identification and prioritization of lands for protection or reduced zoning shall be based on the results of a landscape analysis, or a process like that found in the Green Infrastructure plan*

- The number and design of lots shall be based on minimizing impact to critical areas and protecting natural systems; development shall *incorporate the findings of the landscape analysis during development of the* objectives of the Critical Areas policies rather than maximizing the number of lots; in order to protect critical areas, the full density permitted under the zoning ordinance may not be achieved

- Creative solutions (e.g., flexible lot design, TDRs, and *purchase of development rights* [PDRs]), which may allow the maximum number of lots while protecting critical areas, should be explored

Fish and Wildlife Policies and Aquatic Resources

Policy language for fish and wildlife and aquatic resources may be the easiest to modify. Modifications to typical policy language may simply incorporate the requirement for conducting the landscape analysis, prioritizing lands for protection based on clearly identified criteria, and directing zoning to result in lower impact on high-priority habitats and critical areas. The following are examples of modifications (in *italics* or ~~strikethrough~~) of existing policy language:

- The protection, ~~and~~ enhancement, *or restoration* of wildlife habitat shall be an integral component of the land-use planning process

- The protection, ~~or~~ enhancement, *or restoration* of critical wildlife habitat *and linkages identified through landscape analysis* shall be ~~one of the criteria~~ *a primary criterion* used when evaluating the preservation of open space as part of development techniques, such as clustering, Flexible Lot Design Subdivisions, and creation of TDRs

- Protect critical wildlife habitat and limit fragmentation of habitat that isolates wildlife populations (physically and genetically) by developing an interconnected system of corridors which link critical wildlife habitat *based on a landscape analysis*

- Evaluate wildlife habitat and *linkages based on a landscape analysis, and* develop a classification system which will identify ~~priority~~ habitat to be preserved; the *analysis* shall consider watercourse areas, wetlands, shoreline, riparian areas, tidelands, public open space, forested areas, topography, *aquifer recharge areas, Washington Department of Fish and Wildlife Priority Habitats and Species data,* and intensity of adjacent development

- Structure regulatory processes and permitting decisions so that they reasonably balance natural values with the use of the land *by utilizing a landscape analysis to prioritize lands for protection or special management*

- Collect and analyze information relevant to the function of natural systems *by conducting a landscape analysis as well as collecting information at individual sites*

- Develop a community-wide program to educate the public about alternatives to using and disposing of herbicides, pesticides, and other household chemicals to reduce impacts *to aquatic resources* and other environmentally sensitive areas

- New development, using flexible lot design, should include any *aquatic resources, prioritized habitats and linkages, and regulated buffers* in separate tracts or easements to remain in common ownership

Frequently Flooded Areas and Geologically Hazardous Areas

Through the landscape analysis, frequently flooded areas (FFAs) and geologically hazardous areas can be identified as lands requiring particular zoning limitations in order to protect public health and safety. Policy statements that are "standard" for these types of lands are appropriate to use.

However, FFAs and the processes that occur in these areas such as sediment transport, recruitment of large woody debris, nutrient cycling, and habitat linkages are protected under GMA. *Diehl V. Mason County* (95-2-0073) states, "An FFA designation must be clearly mapped and must include buffers sufficient to protect critical area functions and values." These areas can also function as wetlands and wildlife habitat and provide linkages between landscape processes. Therefore, policy language can be modified to protect the processes and functions of FFAs and geologically hazardous areas, and the wetlands that occur within them, based on landscape analysis.

Natural Resource Lands

Natural resource lands are designated for resource production and may include wetlands and other critical areas, as well as areas in which important landscape processes occur.

Development regulations should require buffers to protect the critical areas within these resource lands.

Typically these areas have already been designated; however, a landscape analysis may identify the linkage between these areas and landscape processes as well as the role that wetlands (and/or restored wetlands) play. For example, protection of shellfish areas is often related to water quality upstream of these resource lands. Wetlands and/or restored wetlands can provide important improvements in water quality. Shellfish growing areas are candidates for designated agricultural lands.

7.3.2 Capital Facilities Plan Element

A Capital Facilities Plan Element includes the analysis and planning for public water, sewer, transportation, and recreation facilities. A jurisdiction has the responsibility to provide water and sewer services, parks and recreation, public safety, transportation facilities such as adequate streets and roads, plus other basic public services and facilities. The Capital Facilities Plan Element includes a requirement to reassess the Land Use Element if funding falls short of meeting existing needs for public services and utilities.

The Capital Facilities Plan Element can address regional water drainage needs, planned parks and recreation facilities, and other capital expenses needed for critical areas protection. Funds to support open space tax assessments, transfers of development rights, conservation easements, and similar needs can be identified in the Capital Facilities Plan Element.

In addition, policies in the Capital Facilities Plan Element can provide guidance on the appropriate conditions and geologic settings in which to use low impact development (LID) practices, referencing such policies in the Land Use Element. The Capital Facilities Plan would state the costs to implement the policies over time, along with alternatives that offer potential cost savings through measures such as LID. LID practices address the control of stormwater and surface water runoff, which is important in protecting wetland hydrology. Traditional and regional stormwater management facilities can also be assessed through the landscape analysis to identify how to minimize adverse impacts of runoff.

Policy language for the Capital Facilities Plan Element in a comprehensive plan can be readily modified to reflect these issues. For example (new language below is in *italics*):

- Designate utility corridors *using landscape analysis to ensure that placement of facilities does not result in permanent impacts to critical areas, their buffers, or habitat linkages*

- Promote the placement of underground utility distribution lines *using information from a landscape analysis to minimize or eliminate permanent or temporary impacts to critical areas*

7.3.3 Rural Lands Element

The Rural Lands Element in county comprehensive plans addresses lands that are not designated for urban growth or lands used for agriculture, forest practices, or mining. It implies lower density land uses with the intention of maintaining the locally defined rural character of unincorporated areas. Measures used to protect and manage rural lands include clustering, density transfer, design guidelines, conservation easements, and other innovative techniques designed to accommodate appropriate rural population densities and land uses.

One of the most significant impacts in rural zones is the increasing tendency to clear residential lots for pastures or viewsheds. The removal of forest cover, as discussed in Chapter 3 of Volume 1, has a significant effect on hydrologic patterns within the contributing landscape. Thus, guidance and policy language within the Rural Lands Element of a comprehensive plan can address site clearing and provide recommendations or requirements for retaining forest cover on lots of certain dimensions.

Typical examples of modified policies for Rural Lands are provided below (new text is in *italics* and deleted words are indicated by ~~strikethrough~~). Note that many of these examples of policies from existing comprehensive plans already incorporate many of the goals in Chapters 5 and 6 of this volume:

- Land use regulations and development standards shall protect and enhance the following components of the Rural Area
  - The natural environment, particularly ~~as evidenced by the health of~~ wildlife and fisheries (especially salmon and trout), *shellfish resources, habitat areas including linkages between habitats as identified as a result of landscape analysis*, aquifers used for potable water, surface water bodies, *wetlands and* natural drainage systems and their riparian corridors
  - Commercial and non-commercial farming, forestry, fisheries *including shellfish aquaculture*, mining, and *home-based and* cottage industries
  - Historic resources, historical character, and continuity including archaeological and cultural sites important to tribes
  - Community small-town atmosphere, safety, and locally-owned small businesses
  - Economically and fiscally healthy rural cities and unincorporated towns and neighborhoods with clearly defined identities compatible with adjacent rural, agricultural, forestry, and mining uses
  - Regionally significant parks, trails, and open space *including corridor linkages identified through landscape analysis*
  - A variety of low-density housing choices compatible with adjacent farming, forestry, mining, *and open spaces,* and not needing urban facilities and services

- The Rural Area designations include areas that are rural in character and meet one or more of the following criteria
  - Opportunities exist for significant commercial or non-commercial farming and forestry (large-scale farms *or more intensive small-scale farms* and forest lands are *usually* designated as Natural Resource Lands)
  - The area will help buffer nearby Natural Resource Lands from conflicting urban uses
  - The area is contiguous to other lands in the Rural Area, Natural Resource Lands, *wetlands, aquifer recharge areas* or *lands identified as critical habitats, habitat linkages or aquatic resources based on a landscape analysis*
  - There are major physical barriers to providing urban services at reasonable cost, or such areas will help define the outer limits for providing urban public services and infrastructure
  - Significant environmental constraints make the area generally unsuitable for intensive urban development

7.3.4 Transportation Element

The Transportation Element is focused on implementing the Land Use Element and addressing intergovernmental coordination of regional transportation facilities and strategies. It is important that the environmental impacts of existing and planned transportation strategies and facilities be addressed in a comprehensive way.

By using the results of a landscape analysis, additions or revisions to existing transportation facilities can be planned to avoid or minimize additional impacts to critical areas and areas that support environmental processes at all geographic scales. Addressing regional transportation issues within the context of landscape information can 1) identify areas that should be avoided, 2) limit habitat fragmentation, and/or 3) facilitate linkages along rights-of-way.

In addition, an Alternative Futures analysis can identify the logical consequences of configuring transportation corridors in various ways. It is possible to anticipate long-range impacts and plan for the compensation for unavoidable effects in advance of the impacts. Jurisdictions can use this approach to identify opportunities to implement Low Impact Development techniques to decrease impervious surfaces by requiring surface parking lots (including retrofits) to be pervious and infiltrate precipitation and water run-off as appropriate to the soil and geology in the area." (For the January 2005 Puget Sound Action Team *Low Impact Development Technical Guidance Manual for Puget Sound* see http://www.psat.wa.gov/Publications/LID_tech_manual05/lid_index.htm.)

One of the requirements for the Transportation Element is financial planning. The Transportation Element has to ensure that, when combined with the Capital Facilities Plan Element, the true costs of planned public works are known in advance of rezoning and commitments to build. This type of analysis can be conducted through an

Alternative Futures assessment, where various costs (economic, community, as well as ecological costs) are determined and compared to help a community make informed choices.

7.3.5 Parks and Recreation Element

This element addresses active parks and recreation opportunities within the community and must be consistent with the Capital Facilities Plan. It may incorporate assessment of the need for organized sports fields, athletic fields, pools, beaches, skateboard parks, etc. It can incorporate passive recreation such as photography or bird watching, as well as other types of recreation such as hiking or mountain biking, or those elements can be contained within a separate Recreation Element.

7.3.6 Economic Development Element

Many jurisdictions are including an Economic Development Element. Some communities are drawing the links between a healthy environment and attracting tourist recreation spending, or building on the "watchable wildlife" program of the Department of Fish and Wildlife.

7.4 Optional Elements of Comprehensive Plans

7.4.1 Conservation Element

As noted in the beginning of this chapter, a jurisdiction may choose to add optional elements to its comprehensive plan that go beyond the mandatory elements, in order to more fully reflect the values and goals of the community. The GMA is open regarding potential elements that can be included as optional.

One optional element that can address the protection of critical areas is a Conservation Element. It can provide an alternative for jurisdictions that are not able to approach all of their comprehensive planning from the foundation of a Green Infrastructure plan or Alternative Futures analysis (discussed in Chapter 6). This can be an element within a comprehensive plan or it can take the form of an independent Conservation Plan. Unlike an Open Space Plan that protects resources through acquisition, the Conservation Element or Plan establishes a method or mechanism to protect and/or restore resource lands through incentives (such as tax credits). Programs such as the U.S. Department of Agriculture's Wetland Reserve Program, the Natural Resources Conservation Service's Conservation Reserve Program, as well as options offered through local land trusts, can also be used in relation to a Conservation Element. Whenever possible, lands to be managed in this way should be identified through landscape analysis or a Green Infrastructure plan.

A Conservation Element is different from the open space approach traditionally used in local planning. The difference is that Open Space Plans typically focus on protecting lands that are valued for aesthetic, recreational, and habitat features primarily through the acquisition of properties by the local parks department. The open space approach can fall short by 1) not including a broader definition of important features worthy of preservation for their contributions to landscape processes, and 2) not including sites that could be restored or enhanced to return processes and improved functions to the landscape.

During the development of a Conservation Element or Plan, sites for both potential acquisition and restoration can be identified. Appropriate sites, such as wetlands in key locations that have a high performance of functions or that support landscape processes, can be located using information generated during landscape analysis. Specific sites can be assessed using tools such as the Washington State wetland rating systems (Hruby 2004 a,b) and the Washington State wetland function assessment methods (Hruby et al. 1999, 2000).

A Conservation Plan should be implemented through both regulatory and non-regulatory components of a program to preserve and restore landscape features identified within the plan. Together, Conservation Plans and non-regulatory components of a program are important additions to comprehensive planning and regulations in providing protection for wetlands and other important landscape features. The tools a local jurisdiction needs to consider using for developing and implementing the non-regulatory component are discussed in Chapter 9.

7.4.1.1 Natural Setting Element Used in Yakima County

Yakima County has a Natural Setting Element that could be considered as part of a Conservation Element or Plan. The text below is taken from Yakima County's Natural Element (http://www.co.yakima.wa.us/planning/pdf/plan2015.pdf). The text has been modified to incorporate the recommendations of this volume (edits are shown in *italics* and ~~strikethrough~~):

- The Natural Setting Element serves ~~two~~ *three* purposes. The first is to clarify the relationship between the natural environment and our built-out surroundings. The second is to secure a balanced or sustainable approach to future development. *The third is to ensure that balanced and sustained economic growth is planned to ensure the existence of long-term landscape processes that sustain the natural environment and help define our community.* To help complete these purposes, the following guiding principles and assumptions were used:
  - Our cultural landscape "where we work, live and play" is shaped by our natural surroundings; *therefore, our future landscape must include the space and configurations needed to sustain the natural surroundings*
  - Our economic base of agriculture and forest products is dependent upon the County's natural setting and its resources

- In order to protect the long-term capacity of the environment to support growth, we need to understand the limits of natural systems *and we need to understand how our choices influence the processes that control those natural systems*
- Responsible growth requires us to work with and within our natural setting; we must work with nature rather than against it; *thus we must analyze, at a landscape scale, the processes that sustain the natural system and plan our future growth by working with nature*
- We must recognize our limits; humankind's problems, especially in regards to the natural setting, cannot always be solved with better science or a technological fix

7.4.2 Subarea Plans

RCW 36.70A.080 allows for the development of subarea plans as optional elements of a comprehensive plan. Subarea plans are essentially more detailed land-use plans for a specific area and must be consistent with the comprehensive plan. One benefit of subarea plans is that citizens typically have increased opportunities for participation.

Some jurisdictions have adopted subarea plans that emphasize elements of the comprehensive plan that are important to that specific area, whether for reasons of economic development or environmental protection. They provide local governments the opportunity to fully incorporate Smart Growth and the results of landscape analysis (e.g., Green Infrastructure or Alternative Futures) into the comprehensive plan. For example, Alternative Futures analysis in Kitsap County's Chico Creek (discussed in Chapter 6) resulted in a detailed subarea plan that addressed many of the issues covered in this chapter.

For jurisdictions that are not currently amending comprehensive plans to reflect the recommendations in this volume, it may be timelier and equally effective to incorporate the recommendations within subarea plans. This is particularly true for areas within the jurisdiction with a high density of critical areas. Planning only for a subarea does, however, reduce the geographic area that is included in landscape analysis. Therefore, it is advisable to have at least a cursory understanding of the landscape and its processes beyond the subarea as well as within its boundaries.

Plans and policies (discussed in this chapter as well as Chapter 6) are only some of the solutions that can be identified and developed as a part of Step 2, Prescribing Solutions. Regulatory and non-regulatory tools are identified and developed as common solutions. Chapters 8 and 9 discuss these tools in detail.

Chapter 8

Prescribing Solutions: Regulatory Tools

8.1 Introduction

This chapter describes the regulatory tools that can be used to protect and manage wetlands. It is intended to assist local governments in developing these tools. As with plans and policies described in Chapters 6 and 7, developing regulations is an important part of Step 2, Prescribing Solutions, in the four-step framework in a program to protect wetlands (Figure 8-1).

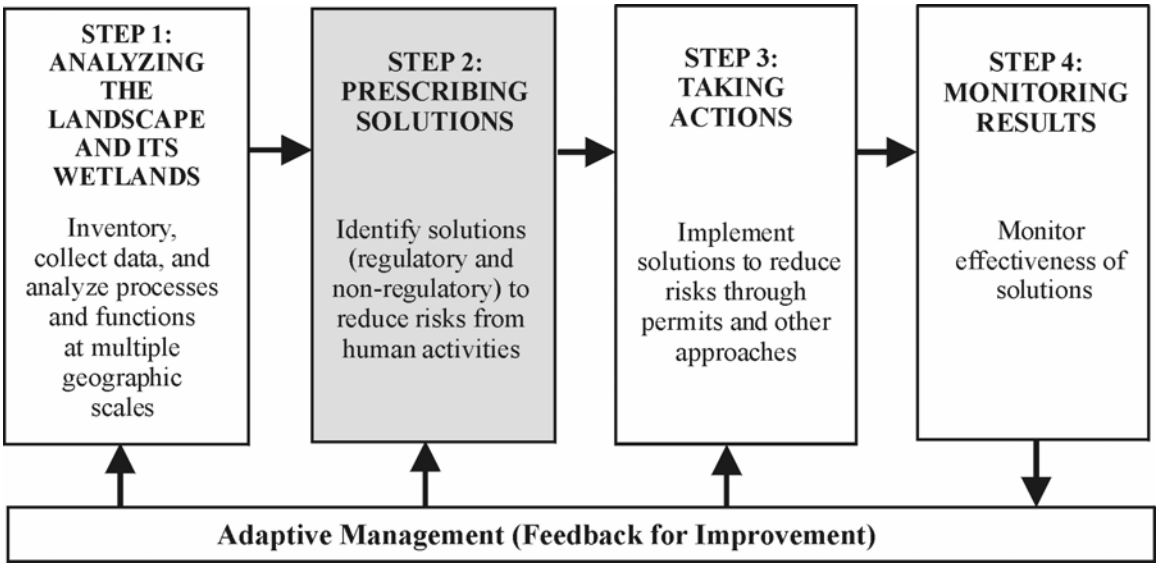

Figure 8-1. Developing regulations is part of Step 2 in the four-step framework discussed in this volume (shaded box).

Although, regulatory tools are only one part of the package of solutions recommended to protect wetland functions and values from future human impacts, they are usually the "backbone" of any wetland protection program implemented by local government.

As described in Chapter 2, the Washington State Growth Management Act (GMA) specifically requires that local governments adopt development regulations that include the best available science to protect the functions and values of critical areas (RCW 36.70A.172). These regulations are one of the primary means of implementing the goals and policies in the land-use plans of local governments.

Historically, most local governments have relied upon regulation as the sole means of protecting wetlands. A regulatory permitting component can, in fact, be very effective at limiting some of the adverse impacts associated with new development (if based on an

understanding of the scientific literature in Volume 1). However, the synthesis of the science makes it clear that reliance upon a regulatory approach using case-by-case decision-making at the site scale as the sole means of protecting wetlands will result in loss of wetland functions. Wetland regulations are most effective in preventing direct physical loss of wetland area and functions resulting from a change in land use, but regulations that focus on the site scale are not effective in addressing the indirect and cumulative impacts from larger-scale changes in landscape processes.

Using the information generated by landscape analysis described in previous chapters can help in developing regulations that protect not only the functions of individual wetlands, but protect some landscape processes as well. Although beneficial at larger scales, this is best done at a sub-basin or subarea scale, where specific regulations can be developed to prevent degradation of landscape processes and to target protection of connected habitats.

Section 8.2 of this chapter discusses several factors that should be considered when establishing regulations, such as balancing predictability with flexibility, the expertise of in-house staff to review wetland reports and permits, the assessment of risk, and the use of a separate permit for critical areas vs. incorporating provisions for critical areas throughout a jurisdiction's code. Section 8.3 discusses the specific elements that need to be addressed in local regulations, such as identifying wetlands, the applicability of regulations and permitting schemes, regulated activities and exemptions, wetland ratings, buffers, etc. The last section of this chapter (Section 8.4) briefly describes how to monitor the regulatory aspects of a protection program.

Regulations target site-scale activities (e.g. clearing vegetation, disturbing the soil, changing the movement of surface water and groundwater, and development together with its supporting infrastructure) that can impact adjacent and nearby wetlands (see Volume 1, Chapters 2 through 4). As discussed below and in Chapter 5 of this volume, such activities also have the potential for altering landscape processes and impacting wetlands not in the immediate vicinity of the alterations.

Important information is provided in appendices

Supporting information and additional detail on the topics discussed in this chapter are provided in a series of appendices (8-A through 8-H), listed in the shaded box on the next page. They contain examples of implementing language (e.g., for regulations, buffers, wetland ratings, criteria for technical experts, etc.) and other information. ***Chapter 8 and all of these appendices should be reviewed before a local jurisdiction decides to use any of the recommendations in this document in its critical area regulations.***

Appendix 8-A. An Overview of Ways to Protect and Manage Wetlands synthesizes the information available on what is needed to protect or replace wetland functions. The discussion is organized by the three major groups of functions (water quality, hydrologic, wildlife habitat) and by the different types of wetlands with other characteristics used in the Washington State wetland rating systems (e.g., bogs, Natural Heritage wetlands, etc.).

Appendix 8-B. Recommendations for Wetland Language in a Critical Areas Ordinance contains specific recommendations for ordinance language in a format similar to that used in many local critical area ordinances. This appendix revises the wetlands regulatory code language found in Appendix A of *Critical Areas Assistance Handbook* published by the state's Department of Community, Trade, and Economic Development (November 2003).

Appendix 8-C. Guidance on Widths of Buffers and Ratios for Compensatory Mitigation for Use with the Western Washington Wetland Rating System provides detailed guidance on buffers, ratios for compensatory mitigation, and other measures for protecting wetlands that are linked to the *Washington State Wetlands Rating System for Western Washington-Revised* (Hruby 2004b).

Appendix 8-D. Guidance on Widths of Buffers and Ratios for Compensatory Mitigation for Use with the Eastern Washington Wetland Rating System provides detailed guidance on buffers, ratios for compensatory mitigation, and other measures for protecting wetlands that are linked to the *Washington State Wetlands Rating System for Eastern Washington-Revised* (Hruby 2004a).

Appendix 8-E. Rationale for the Guidance on Recommended Widths of Buffers and Other Methods for Protecting Wetlands explains the rationale for the recommendations about buffers presented in Appendices 8-C and 8-D. It discusses why buffers of certain widths are recommended for wetlands that perform functions at different levels or for specific wetland types (e.g., bogs, etc).

Appendix 8-F. Rationale for the Guidance on Recommended Ratios for Compensatory Mitigation to be Used with the Wetland Rating Systems explains the rationale for the recommendations about compensatory mitigation ratios presented in Appendices 8-C and 8-D. It describes how mitigation ratios should be established based on risk of failure and temporal loss of functions, and can be further refined to reflect the category and type of wetland.

Appendix 8-G. Widths of Buffers Needed to Protect Some Threatened/Endangered/ Sensitive Wildlife Species Associated with Wetlands lists the widths of buffers needed to protect some of the wildlife species associated with wetlands. The species listed are the Federal Candidate, Federal Threatened, Federal Endangered species, State Sensitive, State Threatened, and State Endangered species found in Washington as of February 4, 2005.

Appendix 8-H. Hiring a Qualified Wetland Professional provides guidance on hiring a professional to provide wetlands services such as delineations, functions assessments, permit preparation, etc. It discusses the basic qualifications that should be considered by local governments and provides suggestions for locating a professional.

8.2 Issues in Establishing Regulations

Some of the key questions a local government should ask when establishing regulations that protect and manage wetlands and their functions include:

- Has a landscape analysis been conducted and have plans, policies, and zoning regulations been revised to reflect that information at the landscape scale?
- Are regulations the sole means of protecting wetlands, or are there (will there be) non-regulatory approaches that will help in protecting wetland functions?
- How much is known about the types and extent of wetlands in the jurisdiction and how they function?
- How well do the current zoning and critical area inventory maps incorporate reliable information on where wetlands and other critical areas are located?

Generally, a regulatory program should aim to prevent any further loss or degradation of wetland area or functions, thereby helping to maintain landscape processes as well. However, realistically even a very stringent regulatory program will not completely prevent all impacts to wetlands because some impacts occur as a result of land-use changes distant from wetlands. As discussed in Chapter 2, Section 2.3.4, of this volume, local government regulations may result in localized impacts upon, or even the loss of, some critical areas. However, the overall plan for the resources should result in no net loss of the value and functions of these resources within a watershed, etc. Thus, as previously mentioned, it is important to complement a regulatory permitting approach with planning based on landscape analysis as well as non-regulatory elements (these are discussed in Chapters 6, 7, and 9 of this volume). The following issues should be considered when establishing wetland regulations.

8.2.1 Balancing Predictability with Flexibility

One of the more common complaints about regulations is that they are either too unpredictable or too inflexible. Generally, these two characteristics are at odds with one another. A very predictable (prescriptive) approach provides clear, consistent standards that applicants can rely on. However, such an approach may not allow for flexibility to address site-specific or unique situations from the perspective of the resource or from that of the landowner. On the other hand, a more flexible approach may fail to provide the degree of specificity that allows applicants to have some certainty of the outcome early in the process.

In developing or revising regulations, one must consider how to balance these two competing needs. A balanced approach may set "sideboards" with criteria for selecting within the range of allowable options or a general standard with criteria for deviating from the standard. A more flexible approach implies more discretion on the part of local staff and managers.

8.2.2 Staff Expertise and the Role of Third-Party Review

As just mentioned, an important consideration in determining the appropriate regulations is the capacity of local staff to exercise independent judgment in applying protection standards, especially with a more flexible, less prescriptive approach. Flexibility requires time on the part of staff that are well versed in wetland ecology and management in order to make consistent and defensible decisions based on site- or situation-specific factors (see Chapter 11 for more discussion). Many local jurisdictions cannot afford to have this expertise on their staff and rely upon third-party review by a wetland professional who is retained by the local jurisdiction (usually at the applicant's expense), or through technical assistance from state or federal agencies (see Appendix 8-H on hiring a wetland professional).

8.2.3 Separate Critical Area Permit vs. Provisions Throughout the Code

Although critical areas ordinances are most often used as the sole regulation for wetlands and other critical areas, other code provisions may be directly relevant to the protection and management of critical areas. Some jurisdictions adopt critical areas provisions that establish a distinct permit that is required for any proposed activity within that type of critical area or its buffer. Other jurisdictions place provisions for critical areas and their buffers throughout their code, wherever consideration of impacts on critical areas is appropriate. For example, language addressing wetland/buffer protection may be adopted into clearing and grading regulations. (See Section 8.3.2 for more discussion.)

If a local jurisdiction decides to link wetland protection to other existing regulations and permits (e.g., clearing and grading regulations), it should bear in mind the issues described in the following sections (especially 8.3 and 8.3.2), as applicable.

8.2.4 Risk Management for Wetland Resources

In the end, the primary decision regarding the appropriate type and stringency of regulations for protecting wetlands is one of risk management. The key question is: *How much risk of loss or degradation of wetland functions and values is reasonable given; 1) what is known about the types of wetlands and their functions, 2) the types of land uses and their impacts, and 3) what othe, complementary components of protection, including planning based on landscape analysis and non-regulatory programs, are in place or will be implemented?* The scientific literature does not and cannot say what the appropriate level of risk should be; it can only assess the potential consequences of this type of decision. The final determination of the level of risk that is appropriate is made by government at the local level. (Risk assessment is discussed in greater detail in Chapter 10 of this volume.)

8.3 Important Elements of the Regulatory Component of a Protection Program

The current general approach to wetland regulation at the local level can be summarized as: *Avoid - Buffer - Compensate*. This means:

- **Avoid** direct impacts to a wetland or its buffer to the extent practicable by allowing impacts only when there is no reasonable alternative
- **Buffer** wetlands from indirect impacts through the retention of adjacent vegetated upland
- **Compensate** for unavoidable impacts by requiring the replacement of wetland and/or buffer area and function through the restoration, creation, enhancement, and/or preservation of wetlands and/or their buffers

This approach has been used in areas of the Puget Sound lowlands since 1984 and throughout Washington for the past 10 years. With appropriate protection standards and consistent implementation, such provisions can go a long way toward protecting wetland functions and values that are not strongly linked to landscape processes. For those that are affected by landscape processes, however, the review of the science in Volume 1 indicates that site-specific regulations alone will not protect all wetland functions.

Following is a discussion of the recommended key elements that should be addressed in the regulatory component of any local government's wetland program. For examples of recommended code language for each of these elements, please refer to Appendix 8-B.

8.3.1 Designating, Identifying, and Mapping Wetlands

The GMA requires that local governments designate and protect critical areas including wetlands (RCW 36.70A.170 and 172). The first step in regulating wetlands is to define what is being regulated and specify how these areas will be identified. The GMA provides the definition of wetlands and specifies how to identify and delineate them.

In designating wetlands for regulatory purposes, counties and cities are required to use the definition of wetlands in RCW 36.70A.030 (20):

> *"Wetland" or "wetlands" means areas that are inundated or saturated by surface water or ground water at a frequency and duration sufficient to support, and that under normal circumstances do support, a prevalence of vegetation typically adapted for life in saturated soil conditions. Wetlands generally include swamps, marshes, bogs, and similar areas. Wetlands do not include those artificial wetlands intentionally created from non-wetland sites, including, but not limited to, irrigation and drainage ditches, grass-lined swales, canals, detention facilities, wastewater treatment facilities, farm ponds, and landscape amenities, or those wetlands created after July 1, 1990, that were unintentionally created as a result of the construction of a road, street, or highway. Wetlands*

may include those artificial wetlands intentionally created from non-wetland areas created to mitigate conversion of wetlands.

Wetlands are subject to a local government's regulatory authority if they meet the criteria in this definition. The GMA does not allow flexibility in adopting a modified definition of wetlands.

State legislation (RCW 36.70A.175) also requires local governments to use the *Washington State Wetlands Identification and Delineation Manual* (WAC 173-22-080) in implementing the GMA. The manual is used to identify the actual boundary of a wetland. The manual is based on the 1987 Corps of Engineers wetlands delineation manual and incorporates changes made by the Corps since 1987. Since the Washington State manual and the Corps manual rely upon the same criteria and indicators for hydrology, soils, and vegetation, proper use of either manual should result in the same wetland boundary.

Having reliable information about the location and extent of wetlands in a local jurisdiction is helpful to landowners and to regulatory staff. Reliable information provides greater predictability for landowners and helps ensure that wetlands are accurately identified for regulatory purposes. However, many local governments do not have accurate maps of wetlands within their jurisdiction. Inventory maps that have been checked on the ground can be time consuming and expensive to produce. Although field inventories conducted by local governments are recommended, existing information can be used to produce a useable, if less accurate, map of wetland locations.

Many local governments use a Geographic Information System (GIS) for decisions about planning and land uses and can generate a useful wetland map by combining several digital layers. The National Wetlands Inventory (NWI) can be combined with local soil surveys to produce a map that shows the approximate location, extent, and distribution of many (but usually not all) wetlands in the jurisdiction. The NWI was completed by the U.S. Fish and Wildlife Service and the soil surveys by the Natural Resources Conservation Service (formerly called the Soil Conservation Service). For many areas of the state, the NWI and hydric soil maps are available in digital format.

Two other layers of information that are also useful are 1) the maps of Priority Habitat and Species (PHS), generated from a database established and maintained by the Washington Department of Fish and Wildlife, and 2) the Flood Insurance Rate Maps (FIRMs), developed by the Federal Emergency Management Agency (FEMA). PHS data help identify fish and wildlife issues associated with wetlands that might arise. The FIRMs, although sometimes out-of-date, can be useful when used with other data, particularly when seasonal or forested wetlands may not have been mapped in the National Wetlands Inventory. Few FIRMs are currently digitized, but FEMA is in the process of digitizing all FIRMs for use with GIS.

Paper copies of FIRMs are available by calling toll-free 1-800-358-9616 or through the FEMA website: www.fema.gov (click on "FEMA flood map store"). Digitized FIRMs should be completed by around 2010 for the entire state but by 2008 for the urban centers. At this time, there are only two jurisdictions in the state (Whatcom County and the City of Anacortes) that have digital FIRMs that meet the current standards (i.e., GIS-based digital maps).

When superimposed, all of these maps can serve as a useful starting point for identifying the general location of areas that are likely to be wetlands in a planning area. However, as already mentioned, local field-based maps are superior because of the potential inaccuracy of the NWI and soil surveys, which are based on interpretation of aerial photographs (some 15 to 20 years old). This makes the existence of some wetlands as well as the extent of others hard to identify. Typically, the hydric soils maps have more field verification than the NWI maps, although aerial photography is the main source of information for both. In addition, wetland maps cannot replace the need for site- or parcel-scale delineations when activities are proposed that might affect wetlands.

To ensure the protection of wetlands, the regulatory code should contain language that clearly states that wetlands are to be regulated as they are defined in code and designated on site, not as they are mapped during inventories. In other words, areas that meet the regulatory definition of a wetland are regulated even if they are not mapped.

It is also important to understand how wetlands function and how they interact with landscape processes when applying local regulations. See the discussions later in this chapter and its appendices regarding wetland rating systems, as well as Chapter 5 for information on landscape analysis.

8.3.2 Applicability of Regulations

The applicability section of a code clarifies what types of activities the code is intended to regulate. There are two general ways in which protection measures for wetlands and other critical areas can be triggered through codes: 1) wetland provisions are integrated throughout various elements of the development code as applicable; or 2) a distinct permit for a specific critical area (e.g., wetland) is required for activities that may influence them. These two approaches are discussed below, along with a discussion of code language that address applicability and the pros and cons of each. Regardless of the approach selected to trigger the wetland protection, the code should, as mentioned previously, require that a site reconnaissance be conducted to evaluate the presence/absence of wetlands and their extent and to collect other information. This is particularly important given the limitations of wetland inventory maps as discussed above.

8.3.2.1 Protection of Wetlands Triggered by Various Development Permits

Measures used to protect wetlands or other critical areas can be initiated when any development permit (e.g., a grading, rezone, building, subdivision, short-plat permit, etc.) is required by the local jurisdiction. The code can be written to automatically allow the wetland provisions of the code to be applied to a permit when the applicant submits it. Thus, the law can be written such that the submittal of each development permit allows staff to review and condition the application with the regulatory standards for wetlands from the code.

Applicability language

Using this approach, the applicability section of the code should state that the critical areas provisions of the jurisdiction apply to "any permitted activity if a wetland or its buffer is present on the subject property, or the proposed actions could result in adverse impacts to offsite wetlands and/or their buffers." The language can specify that "all development permits" are included, or the code can specify which development permits trigger the critical area provisions. Such language makes it clear that any action within the jurisdiction that requires a permit (e.g., grading, rezoning, building permit, subdivision, etc.) will be subject to the protection measures in the critical areas code.

For example, some jurisdictions apply critical area provisions to all newly formed lots created **after** the critical area provisions have been implemented or revised (i.e., the applicability language cites the date of the adoption of the new provisions). The jurisdiction can require that all short-plats and subdivisions abide by the new wetland protection standards, **and** they may exempt single-family building permits from wetland review for such new lots. This means that the new lots will have the required critical area setbacks and buffers embedded into them, so the review of building permits for single-family homes is not necessary to assure that they meet the provisions of the code.

This also means that lots that were created **prior to** implementation of the current critical area standards (i.e., "grandfathered in") **may not** be subject to the new provisions (e.g., wetland rating, buffers, and setbacks, etc.) if it would deny all reasonable use of the parcel. This is one means to address reasonable-use provisions when new standards could possibly influence the use of an existing lot that was created under less restrictive standards. Although this may seem like a lessening of regulatory standards, it is a pragmatic approach to deal with the issue of reasonable use. This language also makes it implicit that any proposal to create new lots (e.g., a short-plat or long subdivision) requires implementation of the new standards.

Applicability language for development permits can also be modified to reduce the threshold that triggers a permit (such as a certain acreage) to zero for actions that pose a risk to wetlands and/or their buffers. For example, clearing of vegetation that falls below a minimum square footage (threshold) established for a clearing and grading permit would not trigger the requirement for the provisions for wetlands in the clearing and grading permit. However, the applicability section of the clearing and grading code can

readily be amended to note that, "There is a zero threshold for any activity which may pose an adverse impact to wetlands and/or their regulated buffers; such activities will trigger the requirements of a clearing and grading permit." By this means, existing code language can simply be modified to extend the provisions for wetland review and conditioning to actions that would otherwise not trigger the underlying permit requirements.

Pros and Con

A benefit of this approach is that no new permitting mechanism needs to be established; review and conditioning for critical areas is linked directly to existing permit processes that applicants are already familiar with. Many jurisdictions are already employing this method in their codes, and thus major code revisions and changes in processes used to review permits would not be required. Some development permits (e.g., subdivisions and some rezones) trigger State Environmental Policy Act (SEPA) determinations that may provide a mechanism for greater analysis and public input in the decision-making process than a permit process that is for wetlands only.

Initiating critical area provisions through development permits requires coordination between wetlands staff and the staff who condition and issue development permits (if they are different people). Such coordination is needed to ensure consistency in the provisions of approval for permits. The option of not having a separate wetland permit may require additional review fees for fee-supported staff (as would a distinct wetland-only permit), and may or may not require additional review time compared to a distinct wetland-only permit. There is a risk that the timing of approving multiple permits may lengthen the time required to process an applicant's permit.

For an application to be subject to wetland review and conditioning, some type of development permit (e.g., clearing, grading, filling, etc.) must be triggered. If no development permit is required for an action, no wetland review process can be legally initiated, unless the applicability language is modified as noted above.

8.3.2.2 Separate Critical Area Permit

A separate process for critical areas permits means that an applicant would be required to obtain a separate and distinct wetland (or critical areas) permit whenever a wetland or its buffer is located on the site of a proposed action. This is a distinct permit that would be required **in addition** to any other development permit for a parcel. The applicability of this permit is linked to the presence of the critical area or its buffer on a site. The standards for when a permit would be required should be the same as the provisions for the development-related permits, including zero thresholds for actions such as grading, clearing of vegetation, or other physical alterations.

Applicability language

Code language can be drafted for a wetland permit that identifies the activities that trigger the need to obtain the permit. The language would have to specify actions, development

permits, and/or thresholds of actions that would trigger a review according to the provisions of obtaining a permit. Unlike the previous option, this applicability section would have to include **all** actions or thresholds that would trigger the wetland permit: In the previous option, the applicability language of each existing development permit/action is modified to include wetland provisions. A discussion and description of suggested regulated and exempted activities follows in the Section 8.3.3.

Pros and Cons

Using a distinct wetland or critical areas permit involves many of the same issues described for the first option. The advantage of a wetland-specific permit is that it allows staff to clarify conditions of approval and perhaps, if the mechanism is established, to provide clarity for monitoring and enforcement with wetland permits. If the jurisdiction sets up a monitoring program, which is staffed to ensure that approved wetland permits are tracked and the conditions implemented, then a wetland-specific permit could facilitate such tracking and response**.**

A wetland-specific permit requires wetland staff to coordinate all conditions from all development permits for a particular project to ensure consistency for wetland protection. A wetland-specific permit could possibly result in higher permit and review fees. It should be assumed that a jurisdiction would either hire technical staff to implement a distinct permit program, or require an applicant to pay for review/conditioning of a permit by a third-party professional. The fee structure of the jurisdiction would determine whether fees would be higher for processing a wetland-specific permit compared to that needed to cover processing of multiple permits when protecting wetlands through the previous option.

There is a risk that the timing of approving multiple permits may lengthen the time required to process an applicant's permit. However, in a worst-case scenario, it is also possible that wetland staff may get backlogged in the case of wetland-only permits, in which case other development permits may be approved and issued before it. (The state law requires a 120-day "clock" for local permit review.)

8.3.3 Exempted Activities, Allowed Activities, and Exceptions

Critical areas ordinances are adopted to protect wetlands and their functions from the many types of activities that can adversely impact them as described in Volume 1. Therefore, local governments should regulate all activities with a potential to affect the functions of a wetland and its buffer. At a minimum, it is important to regulate all activities that would directly impact a wetland and its buffer such as filling, draining, excavating, clearing, flooding, and tilling. Other activities that should be included are herbicide application, stormwater discharges, and water diversions and withdrawals.

However, some activities pose little threat to wetlands and can be exempt from regulatory review or can trigger a lower level of review. Exempt activities should be limited to

those that will not have a significant impact on a wetland's structure and function (including its water, soil, or vegetation) and those which are expected to be very short term. Local governments should, however, also consider the cumulative impacts from exempted activities.

The scope, coverage, and applicability of a critical areas ordinance should capture the full range of activities that are detrimental to wetland functions. Therefore, exemptions should be supported by the scientific literature and be carefully crafted to minimize the potential for adverse impacts. Likewise, a local government should not assume that an exemption is appropriate in the absence of science to refute the exemption. The language should clearly state whether a given exemption is from applicable standards in the code or whether it is exempt from needing a permit but still must comply with the code.

The types of activities that are excluded from wetland regulation are grouped in to three categories in the example code provided in the *Critical Areas Assistance Handbook,* Appendix A (Department of Community, Trade, and Economic Development (CTED) 2003). They are *exempted activities, allowed activities, and exceptions.* These three categories allow varying degrees of activities or uses either without review, or in a way that avoids the regulations associated with critical areas, as explained in the following paragraphs.

The first category, exempted activities, are those activities that are excluded from critical areas regulations on the premise that they would have little or no effect, or that the activity is an emergency and delay of the action could result in threats to public health or safety. In addition to emergencies, these activities can include passive outdoor activities, forest practices regulated by the state, as well as specific operation, maintenance, or repair activities.

Allowed activities comprise the second category and are those activities that, due to other regulations or previous reviews, are unlikely to result in critical areas impacts. Since these activities are not exempt, the wetland standards continue to apply and the underlying permit could be conditioned to ensure that the activity complies with critical areas protection.

The third category, exceptions, are granted in limited circumstances where a reasonable use permit is issued to only allow the minimum "reasonable" use of the property and avoid a constitutional taking. Refer to Section X.10.150 of CTED's example code provisions for additional guidance on reasonable use exceptions.

The section below discusses the types of activities that are often considered as exemptions in critical area regulations and how they may apply to different types of wetlands. For each, we discuss the relevant scientific findings and provide recommendations for how they should be treated.

- Wetland size
- Size of minimum wetland impact

- Isolated wetlands
- Wetlands that are designated as prior converted croplands
- Irrigation-induced wetlands
- Clearing, grading, and placement of fill
- Ongoing agriculture
- Conversion of wetlands to new agriculture
- Conversion of agricultural lands to other uses
- Removal of noxious weeds
- Forest practices and conversions
- Removal of hazard trees
- Non-compensatory restoration and enhancement
- Stormwater management and wetlands
- Emergency activities

8.3.3.1 Wetland Size

While recognizing that local governments have to make difficult choices about where to expend their efforts, we do not believe it is appropriate to recommend a general threshold for exempting small wetlands in Washington because the scientific literature does not provide support for such a general exemption. Volume 1 (Chapter 5) documents the relationship between the lower levels of protection afforded to small wetlands and the resulting fragmentation and increase in distance between wetlands on the landscape as well as the important functions provided by small wetlands. The loss of small wetlands is one of the most common cumulative impacts on wetlands and wildlife in Washington.

If a local government, however, wants to consider exempting some wetlands under a certain size, this should be done with an understanding of the potential cumulative impacts (e.g., how many acres of wetlands would be affected, what functions would be most affected, how such impacts would be compensated, etc.). Considering and documenting the potential implications is critical to protecting wetland functions. The decision, therefore, is best made after reviewing the information generated from a landscape analysis (as outlined in Chapter 5 of this volume) for the geographic area that would be affected by the exemption.

Limiting the exemption to certain areas (such as Urban Growth Areas or specific sub-basins) and to certain wetland types (e.g., Category IV wetlands, those with non-native species, non-riparian wetlands) will help minimize the risk of losing important functions.

Additionally, it may be important to limit the total acreage of wetlands exempted on a project basis or within a sub-basin.

A more appropriate way to deal with small wetlands would be to exempt projects from the need to avoid small wetlands. This type of exemption should still require that the loss of wetlands be compensated either directly or through an in-lieu fee program.

8.3.3.2 Size of Minimum Wetland Impact

As with exempting a certain wetland size, there is no scientific basis for exempting wetland impacts under any particular size without an analysis of the cumulative effects of the exemption. A study of the management area is needed in order to measure the net result of the exemption as applied over time. If a local government chooses to move forward with an exemption for small area impacts, a restoration program and/or in-lieu fees program should be created to offset the net impacts.

Given the potential for cumulative impacts from exempting small wetlands and small impacts to wetlands, local governments should monitor and report the effectiveness of their wetland provisions or critical areas ordinances to achieve "no net loss." This is discussed further in Section 8.4 of this chapter.

8.3.3.3 Isolated Wetlands

There is no scientific justification for exempting isolated wetlands from regulation (See Chapter 5 in Volume 1). Isolated wetlands are generally defined as those wetlands that are hydrologically isolated from other aquatic features. Hydrologic isolation is not a determinant factor in the function of wetlands. Isolated wetlands in Washington perform many of the same important functions as other wetlands, including recharging aquifers, storing flood waters, filtering pollutants from water, and providing habitat for a host of plants and animals. Many wildlife species, including amphibians and waterfowl, are particularly dependent on isolated wetlands for breeding and foraging.

The current lack of regulation of many isolated wetlands by federal agencies is the result of very different statutory language in the federal Clean Water Act that ties federal regulation to navigable waters and interstate commerce. No such restriction exists under the GMA or any other state laws.

8.3.3.4 Wetlands that are Prior Converted Croplands

There is also no scientific basis for exempting wetlands that are prior converted croplands (PCC) from wetland regulation under the GMA. Wetlands that are designated as PCC provide the same functions as other similarly degraded wetlands. The scientific information on wetlands designated as PCC is briefly discussed below, following a description of these wetlands, and is also addressed in Chapter 5 of Volume 1.

Prior converted croplands are defined in federal law as administered by the U.S. Army Corps of Engineers. PCC are those wetlands that were drained, dredged, filled, leveled, or otherwise manipulated, including the removal of woody vegetation, before December 23, 1985, to enable production of an agricultural commodity, and that:

1. Have had an agricultural commodity planted or produced at least once prior to December 23, 1985

2. Do not have standing water (ponding) for more than 14 consecutive days during the growing season

3. Have not since been abandoned

However, many of the wetlands meeting these criteria are still *biological* wetlands (i.e., they still meet the three criteria for hydrology, soils, and vegetation) and provide important functions.

Local governments cannot exempt wetlands that are designated as PCC in their regulations and rely on the federal exemption to satisfy the best available science requirement in the GMA. Although activities in these wetlands are not regulated under Swampbuster provisions of the federal Farm Bill or Section 404 of the federal Clean Water Act, the GMA requires local governments to regulate wetlands that meet its definition. This definition of wetlands includes PCCs that meet the three criteria in the *Washington State Wetland Identification and Delineation Manual*. It therefore does not distinguish wetlands designated as PCC from other wetlands.

The original assumption behind exempting PCCs from federal regulation was the belief that these wetlands had been so altered they were no longer wetlands or no longer provided important wetland functions. In some cases, PCC have been significantly altered so they provide functions at a level that is minimal. However, in many cases, PCC provide hydrologic and water quality functions (e.g., recharging aquifers, storing flood waters, filtering pollutants from water, etc.) and may provide wildlife habitat or important linkages between habitats. For example, in western Washington, many PCC used for agriculture are ponded during the winter, when overwintering waterfowl are highly dependent upon flooded areas for resting and feeding. Overwintering bald eagles and other raptors, in turn, depend on the waterfowl attracted to these flooded areas.

Local governments that rely on the Corps of Engineers to verify wetland delineations need to ensure that wetland delineations are conducted and verified using the state wetland delineation manual to determine if they are wetlands regulated under the GMA. Once these wetlands are delineated properly, a function assessment can be conducted to analyze the functions being provided by the wetlands. Most wetlands designated as PCC will be Category III or IV wetlands under the state wetland rating systems. The departments of Ecology and Fish and Wildlife recommend that wetlands designated as PCC be regulated similarly to other wetlands (i.e., commensurate with the functions they provide).

8.3.3.5 Irrigation-Induced Wetlands

Some confusion exists as to whether wetlands that have expanded or have been formed due to the influence of irrigation are considered *artificial* and whether they are, therefore, *jurisdictional* (i.e., that is, regulated under federal, state, or local laws). Many of the habitat types with deep soils in eastern Washington have been converted to agriculture. A large portion of this land, particularly in the Columbia Basin, is under irrigation. Additionally, some agricultural areas in western Washington are also irrigated. In many irrigated areas, the groundwater table is higher than it was prior to implementation of irrigation. Many wetlands have expanded or formed adjacent to irrigation conveyance systems and in low-lying areas where irrigation occurs and downslope of irrigated lands.

The definition of wetlands comes into play when trying to clarify the situation. Artificial wetlands are addressed in definitions of wetlands used in the three state laws that regulate wetlands. These laws include the Growth Management Act (RCW 36.0A.030 (20)); the Shoreline Management Act (RCW 90.58.030 2(h)); and the Water Pollution Control Act (WAC 173-201A.020). This definition reads:

> *Wetlands means areas that are inundated or saturated by surface water or ground water at a frequency and duration sufficient to support, and that under normal circumstances do support, a prevalence of vegetation typically adapted for life in saturated soil conditions. Wetlands generally include swamps, marshes, bogs and similar areas. Wetlands do not include those artificial wetlands intentionally created from nonwetland sites, including, but not limited to, irrigation and drainage ditches, grass-lined swales, canals, detention facilities, wastewater treatment facilities, farm ponds, and landscape amenities, or those wetlands created after July 1, 1990, that were unintentionally created as a result of the construction of a road, street, or highway. Wetlands may include those artificial wetlands intentionally created from nonwetland areas created to mitigate conversion of wetlands,*

Basically, this definition means:

1. A wetland must have indicators of three features: water (wetland hydrology), plants (hydrophytic vegetation), and soils (hydric soils). It must have enough water to support water-dependent plants, so the water must be present during the growing season. The presence of water creates low-oxygen conditions that support those specialized plants and also creates unique soil characteristics.

2. That, for a wetland to be non-jurisdictional (artificial) it must meet both of the following characteristics:

    a. Be intentionally created

    b. Be located in a formerly non-wetland (upland) site

The term *intentionally created* and the examples given in the definition require that the artificial wetland not be the result of an accident or an unexpected byproduct of some other intentional act. Therefore, artificial, non-jurisdictional wetlands result from someone intentionally creating a water feature such as a ditch or pond in an area that is non-wetland. The only situation where an artificial, non-jurisdictional wetland results from an unintentional action is when construction of a road (after July 1, 1990) inadvertently creates a new wetland.

The term *non-wetland* means an area where wetland characteristics are lacking—that is, an upland area. Thus, if someone intentionally creates a new water feature, such as a ditch or pond, in an area that was already wetland, the "new" water feature is still under jurisdiction as a wetland.

The following examples may help illustrate real-world situations:

1. A ranch pond was built on a dry hillside to supply water to livestock, and wetland conditions have formed over time. Clearly, the pond meets both criteria for being an artificial, non-jurisdictional wetland: It is an intentionally created water feature in an upland site.

2. Wetland vegetation is found along the edge of an irrigation canal. The canal is an intentionally created water feature. If the canal was dug through uplands, then the wetland within the canal is non-jurisdictional per GMA (though it may be subject to federal regulation). If the canal was dug through an existing wetland, then the wetlands within the canal are jurisdictional.

3. A wetland is found downgradient of a leaking irrigation canal or pipe. The wetland is jurisdictional because it is an unintentional result of digging the canal. However, the canal (or a leaking irrigation pipe) can be repaired or lined to improve water conservation. If the wetland disappears as a result of the improvement, the loss of the wetland is not regulated. If wetland conditions persist, then the wetland cannot be further altered without a permit.

4. A wetland is found within a field that is irrigated. The wetland is jurisdictional because it was not intentionally created. Although filling the wetland would be regulated, changes in irrigation practices (such as changing from flood to drip irrigation) that would dry up the wetland would not be regulated.

5. A wetland is found in a field that is not irrigated, but irrigation water from a field higher up has raised the groundwater table. The wetland is jurisdictional because it was not intentionally created as part of a water feature.

6. Wetland indicators (water, plants, and soils) are found within a stormwater pond. The wetland is not jurisdictional if the stormwater pond was created in an upland. However, if the stormwater pond was created within a wetland, then it is jurisdictional.

8.3.3.6 Clearing, Grading, and Placement of Fill

The scientific literature does not support blanket exemptions for clearing, grading, and placement of fill in wetlands or their buffers without first understanding the direct and cumulative effects of such an exemption. Critical area regulations should be crafted to address these activities because of their significant and direct impacts to wetlands and their functions.

If a local jurisdiction believes it is important to exempt small amounts or areas of filling or grading in wetlands or their buffers, they should provide some analysis to document the potential cumulative impacts of such an exemption and provide some means of offsetting the expected cumulative impacts. This could include in-lieu fee and/or non-regulatory restoration programs to restore wetlands or increase wetland functions, provided that non-regulatory programs are evaluated to ensure that the no net loss goal is met.

To address cumulative effects of multiple small fills or clearings in the same wetland, the threshold for clearing, grading, or filling a critical area or its buffer should be reduced to zero.

8.3.3.7 Ongoing Agriculture

The literature synthesized in Chapters 2, 3, and 4 in Volume 1 demonstrated that agricultural activities can negatively affect wetlands. One of the goals of the GMA is to protect wetlands and other critical areas. Equally important, the GMA seeks to maintain and enhance industries that rely on natural resources, encourage the conservation of productive agricultural lands, and discourage incompatible uses. Designated agricultural lands are one of the three types of natural resource lands defined in GMA for which local governments need to plan.

The purpose of this volume is not to further evaluate or frame the issue of agricultural impacts. It is important, however, to recognize that different types of agricultural practices result in different types of potential impacts. Local governments should consider the types of agriculture being practiced in their watersheds and craft their critical area protection programs to address impacts from agriculture accordingly.

However, given that existing, ongoing agricultural activities take place in already drained and/or actively manipulated wetlands (such as grazed wetlands), impacts from bona fide ongoing agricultural activities are most effectively managed through best management practices.

The departments of Ecology and Fish and Wildlife recommend the use of best management practices (BMPs) and/or conservation plans for ongoing agricultural activities in wetlands.

There are two basic approaches that local governments should consider:

1. **Voluntary use of BMPs with monitoring.** This encourages the voluntary use of BMPs, farm conservation plans, and incentive-based programs to improve agricultural practices in and near wetlands. Local governments work with Conservation Districts or county staff with agricultural expertise regarding technical assistance to willing landowners. They should set up and implement a monitoring program to determine if the voluntary approach is effective. If problems are detected, the jurisdiction should require the use of specific BMPs and the approval of farm conservation plans in order to correct identified problems; OR

2. **Required BMPs and/or farm conservation plans.** These could be approved by an agency or organization with expertise in agricultural practices (such as a Conservation District), with appropriate local government oversight and monitoring. This type of approach is outlined in the *Critical Areas Assistance Handbook* (CTED 2003) where it describes how Whatcom County has approached this issue:

   Some agricultural uses are regulated by state or local government, usually because of a particular environmental concern related to ground or surface water or air quality. For example, Whatcom County regulates pre-existing agricultural activities that impact wetlands, fish and wildlife habitat conservation areas, and aquifer recharge areas or their buffers in conformance with an adopted conservation program. The conservation program is developed to be consistent with the Whatcom Conservation District's best management practice manual and requires the containment of livestock waste. The plan is then filed with both the conservation district and the county, to ensure that the agricultural practices are being implemented. Periodic monitoring of farm activities ensures that the management objectives are being met.

The CTED handbook acknowledges that while regulations provide certainty, they can be difficult and costly for agricultural activities, particularly without the understanding and cooperation of the landowners.

8.3.3.8 Conversion of Wetlands to New Agriculture

Conversion of wetlands that are not currently in agricultural use to a new agricultural use should be regulated by the same regulations as any new development. The scientific literature does not support the conversion of wetlands to new agricultural uses without review and conditioning through a critical areas ordinance.

8.3.3.9 Conversion of Agricultural Lands to Other Uses

A change in use from agriculture to non-agricultural uses should trigger review under the critical areas ordinance. Exemptions and special considerations for wetlands (i.e.,

targeted implementation of best management practices) crafted for agricultural activities should not be "grandfathered" when the land use changes from agriculture to another form of development. A change in use from one type of agricultural activity to another type of agricultural activity should be addressed through best management practices and farm plans.

Of particular concern is that a change in land use may be preceded by an activity that may be exempted by a local government because alterations may occur to the wetland before adequate review takes place. A common example is the exemption in many critical areas ordinances for the maintenance of existing drain tiles and ditches on drained agricultural lands. Ditches and drain tiles require maintenance from time to time in order to keep the water table low enough during the growing season for agricultural production. As long as the lands are being maintained for ongoing agricultural use, the maintenance exemption makes sense, provided that the original depth and dimension of ditches and tiles is maintained.

A critical areas ordinance should specify what constitutes "maintenance," what does not, and what documentation is necessary to prevent inappropriate or unlawful wetland draining activities. A conflict can arise when ditch and tile systems are enlarged or upgraded to effectively drain farmed wetlands so they no longer meet the definition of a wetland. This is a change in management and is the point where the local government has an interest in reviewing this change in use because new areas are being affected by the upgrade to drainage systems. Many agricultural areas often provide important habitat and other hydrologic functions (previously discussed in Section 8.3.3.4 on Wetlands that are Prior Converted Croplands).

Local governments are encouraged to work with agricultural landowners to implement the GMA's goal of protecting and enhancing agricultural lands, as well as provide notice of their authority to regulate converting wetlands, or expanding the extent of conversion, to non-wetlands for agricultural uses. This recommendation is reflected in the language in Appendix 8-B.

8.3.3.10 Removal of Noxious Weeds

Many current regulations that protect critical areas do not require a permit for the control and removal of noxious weeds in wetlands and buffers (as well as other critical areas), provided that the control is done by hand or with light equipment and does not involve the use of hazardous substances. Local governments should retain some oversight authority when more extensive control methods are proposed to make sure that wetland functions are adequately protected.

8.3.3.11 Forest Practices and Conversions

The state's Forest Practices Act (RCW 76.09 and WAC 222) regulates commercial woodlots and forest lands and contains provisions for protecting wetlands. The Act contains less stringent standards for wetland protection for commercial forestry than those required by local governments for non-forest lands through the GMA. The Forest

Practices Act does not protect forested wetlands from harvest and has weaker standards for avoidance, buffers, and mitigation than most local regulations. It provides standards for buffer protection for certain non-forested wetlands and bogs. The assumption in the Forest Practices Act is that many of the affected functions performed by forested wetlands recover during the time they regenerate trees old enough for another cycle of timber harvest.

However, the GMA requires that local governments protect the functions provided by forested wetlands. It is important for local governments to recognize and address the gap in wetland protection between the GMA and the Forest Practices Act. They should provide a framework to ensure compliance with their standards when forest lands are converted to residential, commercial, or other non-forestry uses. The jurisdiction should regulate the conversion of lands when they will no longer be regulated under the rules of forest practices. The regulations should provide guidance on how this issue will be managed in jurisdictions that contain commercial forest lands. It is important to note that the provisions should only apply when forest lands regulated by the Forest Practices Act are converted to other uses. It should not be the intent of the local jurisdiction to make the Forest Practices Act consistent with local government's more stringent requirements for forested wetlands.

8.3.3.12 Removing Hazard Trees

Provisions for the trimming or removal of hazard trees in buffers are legitimately addressed through an exemption to regulations protecting critical areas. Considering public safety is important in balancing exemptions with the goal of protecting critical areas. The needs for limits on the exemption are obvious: The exemption should be limited to situations where the "offending" tree is clearly a hazard, and removing the tree would not adversely affect the functions of a wetland or its buffer. One option is for the local government to involve a qualified arborist who has an understanding of the functions of wetlands and buffers to evaluate a request to remove a hazard tree.

The qualified arborist should establish that the hazard tree presents an imminent hazard and is threatening a structure. Some local governments use the definition in the Forest Practice Rules (WAC 222-21-010(4)) which define a *danger tree* as "any qualifying timber reasonably perceived to pose an imminent danger to life or improved property." This applies to any tree within 1.5 tree-lengths of the structure. The Washington Department of Natural Resources (WDNR) is not, however, charged with administering the requirements in the GMA. Therefore, a local government should not defer the determination of what constitutes a hazard tree, or the review of hazard tree cutting proposals, to WDNR or WDNR standards. Trees removed as hazards should be replaced either in kind or with species that are underrepresented in the community.

The exemption process should not allow for the creation of "view corridors" and the removal of healthy trees in a buffer under the pretext of control of hazard trees. When trees are removed, a restoration plan should be required. In some instances, pruning (not topping) of trees to maintain (not create) a limited view corridor may be considered by a jurisdiction as appropriate. A management plan for a view corridor, prepared by a

certified arborist, should be required by the jurisdiction. The plan should also be reviewed by qualified staff or an arborist paid by the applicant. This approach is recommended to reduce the cases of illegal clearing to create a view, leaving the jurisdiction to deal with an enforcement action.

8.3.3.13 Non-Compensatory Restoration and Enhancement

Provisions for non-compensatory restoration and/or enhancement may legitimately be addressed as exemptions through critical areas regulations. Limits, however, should be defined so that proposals narrowly focused on or managing for a single function are not allowed to occur at the expense of other wetland functions.

Restoration and enhancement activities are considered non-compensatory when they improve wetland functions (and/or increase wetland acreage) and are not meant to compensate for impacts caused by development. Many restoration activities are by definition "self-mitigating" in that they may cause temporary impacts (during construction) that are ameliorated by the significant increase in function resulting from the activity.

Some non-compensatory activities are not beneficial from a landscape perspective because they are narrowly focused or do not fit the hydrogeomorphic setting in which they are carried out. Narrowly focused activities are those that provide benefits to single species at the expense of other wetland functions. For example, in the past some waterfowl management projects have been constructed to significantly increase waterfowl production, while reducing habitat for non-waterfowl species. An extreme example would be the clearing of a forested wetland for the construction of an impoundment to attract waterfowl.

Local governments should not assume that restoration activities supported by other agencies will result in an appropriate tradeoff of functions and should carefully look at the merits of the proposal. Beneficial projects should be encouraged as a means to offset net losses in the regulatory arena, provided that they result in wetlands of the appropriate hydrogeomorphic class and are supported by landscape processes.

Local governments may also consider relaxing some of the procedural requirements typically reserved for compensatory mitigation projects. For example, a requirement for a restriction on an easement or deed for a "native growth protection area" may only serve to needlessly frustrate the proponent of a project that is non-compensatory in nature. It may be appropriate for a local government to set up a separate review process for non-compensatory projects that is focused on facilitating projects while still complying with requirements of their local protection program.

8.3.3.14 Stormwater Management

The use of wetlands for stormwater management should be included in the list of regulated activities. Most wetlands are adversely affected when they are modified to treat and/or detain urban stormwater. The literature, much of it based on research done in the

Puget Sound area, suggests that there are very narrow circumstances under which wetlands can be managed to meet the stormwater requirements of new (and retrofitted) development. While it may be appropriate in some situations to allow a wetland performing at low levels to be used as part of a system for managing stormwater, local review and permitting should be required.

Ecology has published a manual to provide local jurisdictions with technical standards and guidance on stormwater management based on the current state of the science and the best technical information available. The 2001 revision to the *Stormwater Management Manual for Western Washington* includes practices to minimize stormwater impacts on receiving waters, including wetlands, in areas west of the crest of the Cascade Mountains. The manual is used to address the effects of changes in water quality and water quantity on receiving waters such as wetlands. The 2001 Ecology manual should be used by local governments in western Washington to include best available science in developing or revising protection programs for wetlands.

In the manual, Ecology states that stormwater discharges to wetlands "shall maintain the hydrologic conditions, hydrophytic vegetation, and substrate characteristics necessary to support existing and designated uses." To accomplish this, Ecology recommends use of the amended *Wetlands and Stormwater Management Guidelines* published in Appendix I-D of the manual.

Achieving the goal of maintaining hydrologic conditions requires the use of continuous modeling and spreadsheets to track events that exceed recommended water levels in the wetland receiving the run-off. The modeling tools, such as the Western Washington Hydrology Model (WWHM) provided in the appendices of the manual, are available but applying them is difficult. As a result, Ecology intends to add a spreadsheet to the WWHM, to help with tracking these events. The model can be used to develop strategies to protect wetlands and their hydrology from the negative effects of stormwater run-off if it is calibrated for the specific drainage area. Refer to the manual for more details.

Ecology also published a stormwater management manual for eastern Washington (Ecology 2004). The manual is more limited in scope (when compared to the western Washington manual) with respect to wetland management and does not include the management guidelines for wetlands and stormwater contained in the western Washington manual.

Ecology's manual for stormwater management

Details about changes to and requirements of the stormwater manual for western Washington are available on the internet at:
http://www.ecy.wa.gov/programs/wq/stormwater/manual.html.

The manual for eastern Washington is available at
http://www.ecy.wa.gov/programs/wq/stormwater/eastern_manual/index.html.

8.3.3.15 Emergency Activities

Local codes typically include provisions for emergency activities. These are intended to provide relief from procedural requirements of the code, namely from the time delays associated with having to obtain a permit prior to responding to an emergency. Local regulations should clearly differentiate between the need to quickly permit the emergency activity and providing any compensation needed for the emergency activity after-the-fact. There is no scientific justification for exempting emergency activities from having to provide compensatory mitigation after-the-fact when the emergency action results in adverse impacts to wetlands (or other critical areas).

8.3.4 Wetland Rating

A wetland rating system is a useful tool for dividing wetlands into groups that have similar needs for protection. The scientific literature makes it clear that wetlands in Washington are very diverse (see Volume 1, Chapter 2). Wetlands occur in a wide variety of locations as a result of very different influences (e.g., geomorphology, geology, water source, etc.) and have a wide range of characteristics that contribute to different types and degrees of functions.

Wetland rating systems allow tailoring of regulations to the protection needs of different types of wetlands or degrees of function. They offer a scientifically defensible approach to assigning protection standards as well as providing a significant degree of predictability for applicants. For example, the widths of buffers and ratios for compensatory mitigation can be determined based upon a wetland rating, in addition to other factors.

A rating system for wetlands should divide them into categories based on understanding how wetlands function and how they are affected by human activities. A rating system should use clear criteria for each wetland category and include methods for determining which category a wetland is in. Without detailed methods, it is not possible to consistently apply rating criteria. The primary factors that should be used to rate wetlands are:

- The **rarity** of the wetland type
- The **irreplaceability** of the wetland type
- The **sensitivity** of the wetland type to adjacent human disturbances
- The **functions** performed by the wetland type

Ecology has revised the wetland rating systems that were previously developed for eastern and western Washington based on current wetland science. The revisions to the rating systems were determined by interdisciplinary teams that included local planners and biologists and have been field tested across the state. If a local government wants to revise one of these updated rating systems or develop its own, it should do so based on

the best available science and should include a detailed method for making site-specific decisions about categorization.

Approaches for applying protection measures by incorporating the wetland rating are discussed in Appendices 8-C through 8-F. The Washington State wetland rating systems are available at http://www.ecy.wa.gov/programs/sea/wetlan.html.

8.3.5 Requirements for Wetland Reports

Local regulations should specify when a wetland report is needed, in regard to requesting a development permit, and what should be included in the report. The Department of Community, Trade and Economic Development (CTED) provides guidance, in Appendix A of their handbook (CTED 2003), regarding what should be included in a wetland report for projects that will likely cause impacts to a wetland and require mitigation. Based on this guidance, such requirements for the preparation of wetland reports include, but are not limited to:

1. Preparation by a qualified professional
2. Use of scientifically valid methods and studies in the preparation of the report
3. Minimum contents for the report, which set the threshold for determining whether it is complete
4. Geographic limits of the study
5. Requirements for compensation, performance standards, construction plans, monitoring and maintenance, contingency plans, financial guarantees, and other details

Some projects may result in minor or "de minimus" impacts which may not require a full wetland report. In such cases, some jurisdictions may choose to implement a two-tiered process to segregate projects with de minimus impacts from those requiring more in-depth review and analysis, thereby limiting the need for comprehensive review of all permits that are submitted. To implement a tiered approach, a local jurisdiction would need to collect all information that is readily available about the site of the project and the wetland to complete an initial analysis to determine if a full wetland report is needed (e.g.. the likelihood of project to have more than de minimus impacts). Appendix F of CTED's handbook includes a "critical area identification form outline" that lists a series of indicators and information that can be used for such an analysis. In most circumstances, a jurisdiction would, at a minimum, need to have a wetland inventory that has included some field verification to determine the accuracy of the inventory.

The departments of Ecology and Fish and Wildlife recommend that the requirements for wetland reports, as outlined in the CTED handbook, be included in a local jurisdiction's critical areas code or the administrative rules adopted for implementing the code. Issues

regarding the technical ability of local staff in reviewing wetland reports are covered in Section 8.2.2 of this chapter.

8.3.6 Mitigation Sequencing

Mitigation is a series of actions that requires addressing each action, or step, in a particular order. This sequence of steps is used to reduce the severity of negative impacts from activities that potentially affect wetlands and to determine what types of impacts may be permitted and what types of compensatory mitigation may be appropriate (see the following section for a discussion of compensatory mitigation).

According to the rules implementing the Washington State Environmental Policy Act, mitigation involves the following (WAC 197.11.768):

1. *Avoiding the impact altogether by not taking a certain action or parts of an action;*

2. *Minimizing impacts by limiting the degree or magnitude of the action and its implementation, by using appropriate technology, or by taking affirmative steps to avoid or reduce impacts;*

3. *Rectifying the impact by repairing, rehabilitating, or restoring the affected environment;*

4. *Reducing or eliminating the impact over time by preservation and maintenance operations during the life of the action;*

5. *Compensating for the impact by replacing, enhancing, or providing substitute resources or environments; and/or*

6. *Monitoring the impact and taking appropriate corrective measures.*

The primary decision to be made with respect to avoidance is one of risk management. For example, using the state's system for wetland rating, impacts to Category I wetlands (which are rare, sensitive to disturbance, irreplaceable, or perform a high level of functions) are higher risk and should have to pass a higher avoidance threshold than impacts to a Category IV wetland. Category IV wetlands are usually significantly degraded, provide a low level of functions, and may be more successfully replaced. If the goal is to protect existing functions, it makes sense to apply more stringent protection to those wetlands that have a higher rating. See Appendices 8-A through 8-F for further discussion of incorporating wetland rating into regulations.

8.3.7 Compensatory Mitigation Requirements

Local regulations need to address how best to compensate for wetland area and the functions and values that will be lost due to the proposed impacts. This is called compensatory mitigation. The term mitigation is defined legally as the six-step

sequencing process described in the previous section, of which compensation is step five. Wetland impacts can be significantly reduced or avoided altogether by following the first four steps in the sequence (i.e., avoiding, minimizing, rectifying, and reducing or eliminating impacts). When wetland impacts are unavoidable, the fifth and sixth steps in the sequence are engaged (i.e., compensating for impacts and monitoring the impact and taking appropriate corrective measures).

Step five, compensating for the impact, requires considerable attention to detail because the issues are complex and the current record for compensatory mitigation is variable (see Volume 1, Chapter 6). Based on the review of the scientific literature in Volume 1, regulations addressing compensatory mitigation need to include the following:

- Standards for the type, location, amount, and timing of the compensatory actions
- Clear guidance on the design considerations and reporting requirements for compensation plans

The last requirement allows the local agency to make a decision about the adequacy of the proposed compensatory mitigation.

Ecology reports on compensatory mitigation

A two-part report on compensatory mitigation was published jointly by Ecology, the U.S. Army Corps of Engineers, and the U.S. Environmental Protection Agency. It is titled *Guidance on Wetland Mitigation in Washington State: Part 1 - Laws, Rules, Policies, and Guidance Related to Wetland Mitigation* (Ecology Publication 04-06-013a, April 2004); and *Part 2 – Guidelines for Developing Wetland Mitigation Plans and Proposals* (Ecology Publication 04-06-013b, April 2004). Access them on the internet at http://www.ecy.wa.gov/programs/sea/wet-updatedocs.htm. (The document is currently being revised).

Part 1 of this document outlines the general policies and requirements of federal and state agencies for compensatory mitigation. Part 2 provides detail on what information should be included in a compensatory mitigation plan.

Local governments are encouraged to adopt mitigation policies consistent with Part 1. This will help ensure consistency between levels of government and streamline the permitting process for applicants. The language in Appendix 8-B of this document is consistent with Part 1. Local governments should reference Part 2 as the standard for what should be included in a mitigation plan.

8.3.7.1 Standards for Compensatory Mitigation

The review of the scientific literature makes clear that compensatory mitigation has frequently failed to adequately replace wetland area and functions (see Volume 1, Chapter 6). The reasons for failure, among others, include:

- Poor site selection

- Poor site design
- Inappropriate or inadequate goals, objectives, and performance measures
- Lack of sufficient water
- Inappropriate water regime
- Poor implementation
- Inadequate maintenance
- Lack of regulatory follow-up

The reasons listed above point to a need for rigorous standards to address the type, amount, and location of mitigation projects that are permitted, and the type and extent of information that must be provided in a mitigation proposal. An adequately trained and funded regulatory staff is also vital for performing permit review, compliance monitoring, and enforcement.

Standards for compensatory mitigation should specifically address the following issues.

Goals of Compensatory Mitigation

The standards need to include a statement about the primary intent of compensatory mitigation. Is it to replace the functions being lost by the permitted impact? Is it to achieve greater area or functions? Are tradeoffs in functions allowed (i.e., allowing replacement with different functions than the functions being lost)? Generally, the goal of compensatory mitigation should be to achieve equivalent or greater area and functions.

Types of Mitigation Actions

Compensatory mitigation typically includes five basic types of activities:

- Creation or establishment of new wetlands where none previously existed
- Restoration of new wetland area and functions where wetlands previously existed (also called re-establishment)
- Restoration of wetland functions in an existing wetland area that is significantly degraded (also called rehabilitation)
- Enhancement of some wetland functions in an existing wetland that may reduce other functions
- Preservation (also called protection/maintenance) of an existing wetland that is otherwise likely to experience degradation (because it is not currently well protected by existing laws)

Standards for compensatory mitigation should specify whether any of these types of activities are preferred over others. Generally restoration (re-establishment and rehabilitation) is preferred because it is the most likely to succeed. Enhancement

typically provides the least gain in functions, and preservation always results in a net loss of wetland area; thus, these types are usually the least preferred.

Replacement of Function vs. Area

Standards should address whether wetland area and function must be replaced on an individual project basis and to what extent tradeoffs in functions can be made. *Tradeoffs* means exchanging some functions in favor of others. It is a good idea to require a minimum of 1:1 replacement of wetland area except in unique circumstances, such as when it can be clearly demonstrated that a lesser area of wetland can provide greater functions than are being lost. It is reasonable to require that compensatory mitigation replace the same functions as those lost except when tradeoffs in functions are identified as desirable in a regional plan. As a general rule, replacement of the same functions on a project basis will help ensure that significant tradeoffs are not made on the scale of a landscape or basin without fitting into clearly identified regional priorities.

Tradeoffs in functions need to be evaluated at the site and basin scale. If a function is effectively being performed in a wetland or in a sub-basin, then it may be appropriate to prioritize a function that is currently lacking or being performed at a low level. For example, a project may affect a degraded pasture near a stream that has been diked. The pasture may provide water quality improvement and limited wildlife habitat (e,g,, small mammals and raptors) but is no longer seasonally flooded, therefore diminishing its hydrologic functions. Extensive diking in the basin may have also significantly decreased the flood attenuation and desynchronization functions once provided by the wetland. Suitable mitigation, therefore, may involve removal of a dike thereby increasing hydrologic functions. This would result in a tradeoff with habitat for small mammals, which would be lost. In addition, as discussed in the next section, the removal of the dike would be off-site in relation to the wetland impact.

A real-life example is the Snohomish Estuary Wetland Integration Plan (SEWIP) (Stanley et al. 1997). The SEWIP allows a tradeoff in the types of functions provided by depressional wetlands behind dikes to those provided by restored estuarine tidal wetlands.

Location of Mitigation

Historically, most regulatory agencies required that mitigation activities be performed on-site (i.e., on or very near the same parcel where the impact occurred). This was based on the belief that the closer the mitigation was to the impact site, the better chance it would have of replacing the functions that were lost. However, recent studies have concluded that this requirement too often has forced applicants to try to fit a mitigation project into an area that makes little ecological sense and is not sustainable (Johnson et al. 2002, Johnson et al. 2000).

Mitigation standards should emphasize that mitigation activities must occur in a location where the targeted functions can reasonably be performed and sustained. For example, the site needs to have an appropriate source of water and allow for control of invasive species, and adjacent land uses need to be compatible with the long-term functioning of

the site. It is difficult to design a wetland for amphibian habitat in a location that is surrounded by dense, urban development and expect it to be sustainable.

Compensatory mitigation should not result in the creation, restoration, or enhancement of an atypical wetland. An atypical wetland refers to a compensation wetland (e.g., created or enhanced) that does not match the type of existing wetland that would be found in the geomorphic setting of the site (i.e., the water source(s) and hydroperiod proposed for the mitigation site are not typical for the geomorphic setting). Likewise, a compensation wetland should not provide exaggerated morphology or require a berm or other engineered structures to hold back water. Excavating a permanently inundated pond in an existing seasonally saturated or inundated wetland is one example of an enhancement that could result in an atypical wetland. Another example would be excavating depressions in an existing wetland on a slope, which requires the construction of berms to hold the water.

Amount of Mitigation

The acreage that should be required as compensation for lost wetland area is one of the most important and most contentious aspects of compensatory mitigation. The review of the science in Chapter 6 of Volume 1 indicates that compensatory mitigation frequently fails to produce the targeted wetland area and/or function, and it can take as long as 20 years to more than 100 years for a newly created or restored wetland to perform some functions.

The acreage of compensation required is usually expressed as mitigation ratios that are commonly used as tools to equalize the tradeoffs between the wetland lost and wetland used for compensation. While the overall goal is to replace lost functions with equivalent new functions, the reality is that it generally takes greater acreage and considerable time to provide equivalent functions. Additionally, some types of compensatory mitigation actions (e.g., enhancement, preservation) provide no new area and only a few new functions. The ratios help address the inherent disparities and act as a kind of "interest rate" to address the temporal loss of functions; there is almost always a significant time lag between when the permitted wetland impact occurs and when the compensatory wetland is fully functioning.

However, every mitigation project is unique, and it is possible to create or restore a wetland and provide greater functions than those that are being lost if the project impact is to a significantly degraded wetland. Additionally, some mitigation projects are more likely to succeed than others, particularly if good hydrologic information is available. Thus, mitigation ratios need to be flexible to address the wide range of situations that are encountered.

The recommended approach is to establish general mitigation ratios based on the wetland category and the type of mitigation activity, and then adjust the ratio on a case-by-case basis to account for project-specific factors. Criteria for increasing or reducing ratios should be specified in the standards used to protect wetlands. This provides some degree of predictability for applicants while retaining the flexibility to make site-specific adjustments.

Suggested code language for mitigation ratios is provided in Appendix 8-B. Guidance on compensatory mitigation ratios for use with the western and eastern Washington wetland rating systems is provided in Appendices 8-C and 8-D, respectively. Appendix 8-F provides the rationale behind these mitigation ratios.

Timing of Mitigation

Generally, mitigation actions are conducted concurrently with or soon after the wetland impact occurs. Standard ratios are typically established based on this assumption. If mitigation is conducted in advance of the impacts, then the risk and temporal loss are reduced and the ratio should be reduced commensurately. If the mitigation is conducted well after the impact, the ratio should be increased.

8.3.7.2 Special Types of Compensatory Mitigation

In addition to addressing the more common mitigation actions (e.g., creation, restoration, and enhancement), local jurisdictions should consider including language in their regulations specifying the circumstances under which special types of compensatory mitigation may be used, such as preservation, mitigation banks, in-lieu fee programs, and programmatic mitigation areas. These types of programs are discussed below.

Preservation

The preservation of existing wetlands as a means of compensating for wetland impacts is highly controversial because it always results in a net loss of wetland area and is perceived as trading one wetland for another one that is already protected. The reality is that some wetland types are not adequately protected under existing laws and can benefit from being placed in public ownership or protected by a conservation easement.

For example, many forested wetlands can be logged under current state laws, and wetlands with significant habitat value are very difficult to protect without large buffers and corridors to connect them to other habitats. Preservation of large tracts of wetlands and uplands can provide benefits that are impossible to achieve using typical regulatory approaches. One way to think about the issue of "net loss" with respect to preservation is that some wetlands are going to experience unmitigated impacts unless they are preserved. In that sense, preservation provides a "net gain" over what would otherwise occur.

Preservation has the following basic advantages as a compensatory mitigation tool:

- Larger mitigation areas can be set aside due to the higher mitigation ratios required for preservation
- Preservation can ensure protection for high-quality, highly functioning aquatic systems that are critical for the health of the watershed and aquatic resources that may otherwise be adversely affected

- Preservation of an existing system removes the uncertainty of success that is inherent in a restoration, creation, or enhancement project

Generally, the use of preservation to compensate for impacts is appropriate only in very limited circumstances. The preservation of a *high-quality* wetland in the same watershed or basin where a wetland loss has occurred, however, is often an acceptable form of compensation when done in combination with other forms of compensation such as re-establishment or creation. See Appendix 8-B for features indicative of high-quality sites.

Note that the use of preservation of wetlands as compensatory mitigation should not allow applicants to circumvent the standard mitigation sequence of avoiding and minimizing impacts first, followed by compensating for unavoidable losses. Additionally, preservation projects should be subject to the same requirements as other types of wetland mitigation (e.g., monitoring and long-term protection). Preservation of wetlands generally requires significantly higher ratios to offset impacts than wetland restoration or creation (see Appendix 8-C and D).

Generally, the preservation of at-risk, high-quality wetlands and habitat may be considered an acceptable part of a mitigation plan when the following criteria are met:

1. Preservation is used as a form of compensation only after the standard sequencing of mitigation (avoid, minimize, and then compensate)

2. Restoration (re-establishment and rehabilitation), creation, and enhancement opportunities have also been considered, and preservation is proposed by the applicant and approved by the permitting agencies as the best option for compensation

3. The preservation site is determined to be under imminent threat; that is, the site has the potential to experience a high rate of undesirable ecological change due to on-site or off-site activities that are not regulated (e.g., logging of forested wetlands). This potential includes permitted, planned, or likely actions

4. The area proposed for preservation is of high quality or critical for the health of the watershed or sub-basin due to its location

In addition, please refer to Appendices 8-B, 8-C, and 8-D for additional criteria and further guidance on the use of wetland preservation in compensatory mitigation.

Mitigation Banks

Mitigation banks offer an opportunity to implement compensatory mitigation at a regional scale and provide larger, better-connected habitat in advance of impacts. Mitigation banking involves the generation of "credits" through restoring, creating, enhancing and, in exceptional circumstances, preserving wetlands and other natural resources. These credits can then be sold to permit applicants who need to offset the adverse environmental impacts of projects that would occur within the *service area* of the bank. A bank's service area is akin to its "market area" or the geographic area in which

credits may be sold or used. Projects that use bank credits as compensation are called *debit projects*.

Wetland mitigation banks have two basic components as follows:

- **Bank site**. The bank is located at the physical site where credits for mitigation are generated by restoring, creating, enhancing, and/or preserving wetlands and associated natural resources.

- **Bank sponsor**. An organization operating under the provisions of a mitigation banking instrument that markets and sells credits, maintains a bank ledger, monitors and reports on the development of the bank site, and provides perpetual protection, management, and other services for the bank site.

Bank sites are normally protected in perpetuity by a legally binding protective covenant such as a conservation easement held by a long-term manager. Bank sponsors must also provide one or more temporary financial assurances to ensure the successful ecological development of the bank and an endowment to fund long-term management of the bank site(s).

Once released for sale, wetland bank credits are sold to permit applicants to compensate for wetland impacts that occur within the service area of the bank. As credits are sold, bankers debit them from the bank's ledger so they cannot be resold. Once all credits in a bank have been sold, the bank is closed.

Mitigation banks benefit the aquatic environment by consolidating numerous small wetland mitigation projects into larger, potentially more ecologically valuable projects. This results in economies of scale that benefit the regulated public, regulatory agencies, and the environment.

Another important feature of mitigation banks is that they are developed in advance of the adverse impacts for which they compensate, which ensures that the bank is ecologically successful before it is used to offset adverse impacts at other sites. Mitigation banks that are properly implemented offer improved ecological performance, lower mitigation costs to permit applicants, and a more streamlined permit process.

To date, few mitigation banks have been approved in Washington. However, as the regulatory agencies develop and implement the process to review and approve banks and gain experience in evaluating proposals, mitigation banks are likely to become more common in Washington.

As with any form of compensatory mitigation, the use of mitigation bank credits to offset impacts to the natural resources should not be considered prior to completing the two mitigation sequencing steps of avoidance and minimization. Then, the regulatory agency must determine whether purchasing credits from a particular bank would provide appropriate and practicable compensation for a proposed impact. In making its determination, the regulatory agency should consider whether any opportunity for mitigation that is environmentally preferable (e.g., on-site mitigation) is available, how

closely a bank's credits correlate with the particular wetland functions that would be altered by a proposed action, and whether using a bank to compensate for a proposed action would be in the best interest of the natural resource, particularly the affected watershed.

Current information on the Ecology's Wetland Mitigation Banking Program is available at http://www.ecy.wa.gov/programs/sea/wetmitig/index.html.

In-Lieu Fee Programs

Mitigation using in-lieu fees (ILF) occurs when a permittee pays a fee to a third party in lieu of conducting project-specific compensatory mitigation, purchasing credits from a mitigation bank, or conducting some other form of compensatory mitigation. This fee represents the expected costs to a third party to replace the wetland functions that would be lost or impaired as a result of the permittee's project. ILFs are typically held in trust by a non-profit conservation organization until they can be combined with other ILFs to finance a project that replaces the lost and impaired functions represented by those ILFs. The entity operating the trust is typically an organization with demonstrated competence in natural resource management, such as a local land trust, private conservation group, or government agency that manages natural resources.

ILF mitigation is used primarily to compensate for minor adverse impacts to the aquatic resources when more preferable forms of compensation are not available, practicable, or in the best interest of the environment. Compensation for projects that result in more substantial adverse impacts is usually provided by project-specific mitigation or a mitigation bank. ILF mitigation may be appropriate when:

- The amount of compensatory mitigation required for a project is too small to justify the cost of designing and implementing project-specific mitigation
- Practicable opportunities to conduct appropriate project-specific mitigation or purchase credits from an approved mitigation bank are not available
- Project-specific mitigation that could be implemented would likely result in a low-performing aquatic system, have a high risk of failure, be incompatible with adjacent land uses, or fail to address the needs of the watershed
- A minor amount of additional mitigation is needed to supplement project-specific mitigation that would not, by itself, fully compensate for a project's adverse environmental impact
- The permit process does not adequately compensate for cumulative effects from a project

ILF mitigation and mitigation banking share many similarities. For example, both types of mitigation allow permittees to fulfill their compensatory mitigation responsibilities by paying a fee to a third party who will accept responsibility for the required mitigation.

Also, mitigation banks and ILF-funded projects must both fully comply with existing federal mitigation guidance and policy, including a requirement for a written implementing agreement that normally includes construction plans, performance standards, monitoring and reporting provisions, a long-term management plan, financial assurances, a protective real estate agreement (e.g., conservation easement), and other measures, as appropriate, to ensure the ecological success of each project.

The fundamental difference between mitigation banking and ILF mitigation is the relative timing of the activities that offset the adverse environmental impacts for which they compensate. With mitigation banks, the environment-enhancing activities are conducted in advance of the adverse impacts, whereas with ILF mitigation, those activities normally are not conducted in advance of the adverse impacts. While specific ILF-funded mitigation projects may not always be identified in advance of project-related impacts, quickly expending collected ILFs to fund mitigation projects should be a high priority for any ILF program. However, regulatory agencies may adjust the size of ILFs to compensate for anticipated delays in expending them.

Local governments interested in developing an ILF program should evaluate the potential for cumulative and unmitigated impacts to hydrologic and water quality functions that may result from the program. Local governments should consider the use of stormwater controls (such as over-sizing ponds and swales) as a way to replace wetland hydrologic and water quality functions on-site and reduce cumulative effects from an ILF program.

Programmatic Mitigation Areas at the Local Level

Another approach for consolidating compensatory wetland mitigation involves directing compensation projects to a *programmatic mitigation area*. Simply defined, a programmatic mitigation area is a site (or series of sites) that have been identified by the local jurisdiction or a state or federal agency as a preferable site(s) for wetland compensation. Wetland compensation projects are constructed separately on the site but are all part of a common design. The programmatic mitigation sites are subject to the same minimum requirements as other compensation sites such as permanent protection, monitoring, restrictions on other activities on the site, etc.

The goal of a program for programmatic mitigation areas to allow the restoration of larger wetland areas that are important to the functioning of a stream basin or watershed because of their position in the landscape. Since many projects require relatively small areas of compensatory wetland mitigation, the programmatic mitigation area program allows the consolidation of these small compensation sites into a larger project.

The following is a summary of how a programmatic mitigation areas work?:

1. The lead regulatory entity (county or city jurisdiction, state or federal agency) identifies an area or areas as priority restoration areas

2. The regulatory entity develops a site development plan for the entire site and may either purchase the site or purchase an easement on the site

3. As projects needing compensation arise, the applicants are directed to perform either certain activities on the site (to aid in the completion of the plan) or directed to implement the site design on specific areas within the overall site

This approach has not been used much in Washington. The closest example available is Kitsap County's work along Clear Creek where several mitigation projects have been completed adjacent and complementary to each other. The county has actively directed compensation projects to the Clear Creek area. Another example is along Mill Creek in Auburn where the Emerald Green Race Track and Washington State Department of Transportation located their compensation sites in an area identified in the draft Mill Creek Special Area Management Plan or SAMP (U.S. Army Corps of Engineers 1997).

8.3.7.3 Impacts to buffers

Impacts to buffers should be handled similarly as impacts to wetlands. Applicants should be required to use all available means of modifying their development proposal, as well as using existing provisions for buffer averaging, before they are allowed to build in buffers. Where buffer impacts are unavoidable, compensation should be required in the form of wetland and/or upland restoration or enhancement.

8.3.8 Buffers

Buffers are defined in many ways (see Chapter 5 in Volume 1) but generally include relatively undisturbed, vegetated areas adjacent to critical areas such as wetlands and streams. The review of the scientific literature in Chapter 5 of Volume 1 indicates that the protection of buffers around wetlands is necessary to protect wetland functions. The scientific literature also provides considerable guidance on buffer characteristics, including widths, which are necessary to protect specific wetland functions. The literature does not provide clear direction on how to structure buffer protection and management programs. However, in addition to providing technical information on buffer effectiveness, the literature provides information that should help guide the development of buffer protection policies and regulations. This information can be summarized as follows:

- Four primary factors should be considered in determining the appropriate width and character of buffers, no matter what the physical setting is:
  - The quality, sensitivity, and functions of the aquatic resource
  - The nature of adjacent land use activity and its potential for impacts on the aquatic resource
  - The character of the existing buffer area (including soils, slope, vegetation, etc.)
  - The intended functions of the buffer

- Site-specific information is needed to determine the characteristics and width of the buffer that will make it effective
- It is important to manage surface water discharges to wetland buffers to ensure effective treatment of pollutants
- Generally, buffer widths "shrink" over time as a result of infringement from adjacent activities

Ideally, this guidance should be incorporated into any local government's buffer regulations. There are, however, many different ways to incorporate this information into a protection program for buffers. The challenge for local governments in Washington is to develop approaches to buffer protection and management that include the best available science and provide a reasonable and defensible means of establishing and maintaining effective wetland buffers.

Suggested code language for buffers is provided in Appendix 8-B. Guidance on buffers for use with the western and eastern Washington wetland rating systems is provided in Appendices 8-C and 8-D, respectively. Appendix 8-E provides the rationale behind the recommended buffer widths.

8.3.8.1 Issues Regarding the Regulation of Wetland Buffers

Regulations for the protection of wetland buffers should address a number of issues:

1. Standards for buffer characteristics and width
2. Criteria and procedures for varying from a standard
3. Allowable uses within buffers
4. Best management practices to enhance and ensure effective buffer function
5. Provisions for the delineation and demarcation of buffers and their maintenance over time

In most cases, the primary concern will be "how wide does the buffer need to be?" This issue dominates any discussion of buffer regulation and generates the most conflict. However, before determining appropriate standards for buffer widths, a local government needs to decide how best to balance the need for a predictable and cost-effective approach with the desire for an approach that is both flexible and responsive to specific situations.

The options for regulatory approaches to buffers range from variable-width buffers that are determined case-by-case based on multiple site-specific factors, to fixed-width buffer standards. Between these two extremes, there are many intermediate options that combine some elements of each.

Variable-Width Approach

The case-by-case, variable-width approach is probably the most consistent with what a review of the scientific literature reveals about buffer effectiveness (see Chapter 5 in Volume 1). This approach usually requires the development of a detailed formula and methodology for considering site-specific factors such as wetland type, adjacent land use, vegetation, soils, and slope. By considering all relevant site-specific factors prior to determining the appropriate width of the buffer width, this approach helps ensure that the buffer is adequate to protect wetland functions without being any larger than is necessary.

However, this approach is time-consuming, costly to implement, and provides a less predictable outcome. It requires either that the applicant hire a consultant to conduct the necessary analysis, or that the government agency staff conduct the analysis. In either event, the local government staff must have appropriate training and expertise to conduct or review the report produced. In addition, this approach initially requires considerable effort when the formula and methodology for site-evaluation is developed. This approach also does not provide any predictability for applicants. They have no idea how large a buffer may be required until considerable time and money are invested in the analysis. Using a case-by-case, variable-width approach can also result in attempts to manipulate the site-specific data, lead to frequent haggling with applicants, and create the perception that buffer widths are determined in an arbitrary and capricious manner.

Fixed-Width Approach

By contrast, a fixed-width approach provides predictability and is relatively inexpensive to administer. The downside of this "one-size-fits-all" approach is that it results in some buffers being too small to adequately protect wetland functions and some buffers being larger than necessary to protect wetland functions. Over time, this inequity may erode public and political support for the buffer program. Frustrated landowners can point to the "over-regulation" of those buffers that are larger than necessary, while environmentally-minded citizens can point to those buffers that are smaller than needed to protect wetland functions.

It also is difficult to determine an appropriate standard width, because no single-size buffer can be demonstrated to protect all wetland types adequately in all situations unless that standard width is very large. Furthermore, it is difficult to argue that an approach using fixed widths includes the best available science since the scientific literature clearly recommends different buffer widths based on a variety of different factors. While no local governments in Washington currently use a single, fixed-width approach, there are several states that do (e.g., California, New Hampshire, New Jersey).

Combining the Fixed-Width Approach with Site-Specific Variables

There are several ways to modify an approach using standard, fixed widths to incorporate some of the factors that contribute to the effectiveness of buffers. Some drawbacks of the fixed-width approach can be rectified by using a wetland rating system that divides wetlands into different categories based on specific characteristics. Then, different

standards for buffer width can be assigned to each category. This approach provides predictable widths, yet allows some tailoring of buffer widths to wetland functions.

For example, as previously mentioned, the Washington State wetlands rating systems divide wetlands into four categories based on rarity, sensitivity to disturbance, irreplaceability, and functions. This hierarchical rating allows one to establish larger standard buffer widths for those in higher categories wetlands and smaller standard buffers for those in lower ones. Most local governments in Washington currently designate buffer widths based on the state wetland rating systems or a rating that is similar.

Another way to address site-specific factors while using fixed widths is to have different widths based on the type of adjacent land use, thus incorporating the four factors, discussed earlier, that are known to influence the effectiveness of buffers. A buffer regulation could require a larger buffer width for adjacent land uses with intense impacts and a smaller buffer width if the impacts from adjacent land uses are low. This strategy can be combined with a wetland rating system to provide a more scientific and defensible approach.

Other critical factors, such as the characteristics of the buffer itself and the functions of the buffer that are desired, can be addressed by establishing criteria and procedures for varying from a standard width. This approach allows for some site-specific tailoring of the standard widths on a case-by-case basis without the need for developing a detailed formula or methodology for determining the widths. In this approach, criteria for increases or reductions from the standard buffer width are developed, and the applicant or any other interested party is given the option of "making a case" as to why the standard buffer width should be increased or decreased. Agency staff then evaluate the proposal against the criteria and decide if such a deviation is warranted.

The criteria for allowing a deviation from the standard buffer width should include the various buffer characteristics that in the scientific literature have been determined to be most important. These include slope, soil type, vegetative cover, and/or the habitat needs of particular wildlife species. For reducing standard buffer widths, an applicant should have to demonstrate that a smaller buffer will protect the functions and values of the wetland. This will generally require hiring a qualified expert and preparing a site-specific report for the local government's review and approval. It is also important to have a minimum buffer width below which the buffer cannot be reduced.

Protecting wildlife species that are threatened, endangered and sensitive

Threatened, endangered, and sensitive (T/E/S) species need specific protection, but this protection cannot be accomplished using the protection measures linked with wetland rating systems. If a T/E/S species is found living in or using a wetland, the appropriate state or federal agency should be consulted to determine what is necessary to protect that species. This information can be considered an "overlay" on the wetland rating. A wetland containing T/E/S species should be protected to meet the requirements of the species as well as the measures associated with its rating category. The T/E/S species using the wetland may need larger buffers or other considerations (e.g., no disturbance during the nesting season).

For example, a Category II riverine wetland that provides overwintering habitat for endangered Coho may need larger buffers than those recommended for a Category II wetland that would protect fish that are not T/E/S species.

For these reasons, it is important that wetland rating forms be used in conjunction with detailed guidance on using the rating forms**. Inadequate protection for listed species may result if rating systems are misapplied.** See Appendix 8-G for buffer widths for some threatened, endangered, or sensitive wildlife species associated with wetlands.

8.3.8.2 Reasonable Use Criteria

Another situation in which standard buffer widths may need to be reduced on a case-by-case basis is when protection of the buffer will result in a property owner being denied reasonable use of his/her land. For example, if a landowner has a one-acre parcel that was zoned for one single-family residence and a wetland covers 80% of the parcel, protection of a buffer around the wetland might mean that the parcel is rendered undevelopable. In this case, the landowner would have a strong case that protection of the wetland and buffer would deny him/her all reasonable use of the property. However, if the buffer were reduced, it may be possible to construct a single house on the property and avoid a "takings" claim.

Thus, critical area regulations should include a provision allowing for buffer reduction in situations where reasonable use would be denied. Such a provision should include requirements that the applicant demonstrate that there are no feasible alternatives to reducing the buffer such as revising the development design, that critical wetland functions or public health and safety will not be impaired, and that the inability to derive reasonable economic use of the property is not the result of the applicant's own actions. For example, a landowner may divide the property in a way that created an unbuildable lot after the adoption of critical area regulations.

Reduction of wetland buffers increases the risk that the remaining buffer will be degraded and encroached upon over time. The allowance for the reduction should be coupled with

requirements for permanent fencing and revegetation. Periodic monitoring may also be necessary. Significant reductions in buffers may require off-site mitigation for the reduced buffer.

8.3.8.3 Buffer Averaging

Buffer averaging is a tool for balancing buffer protection with specific site needs for development, or for tailoring a buffer to maximize protection of natural features in the wetland or surrounding upland. It allows a buffer to vary in width around a given wetland. For example, if the standard width for a buffer around a wetland is 100 feet, buffer averaging would allow the width to vary between a minimum and a maximum width but require that the buffer area average 100 feet in width. Typically this is done to allow development to occur closer than usual to the wetland in order to fit a particular development "footprint" onto a given site. However, it can also be used to protect a natural feature (e.g., a stand of trees or snags) that otherwise would fall outside of the standard buffer. Buffer averaging can also be used to provide connections with adjacent habitats or to address those situations where pre-existing development has reduced a buffer area to a width less than the required standard.

Criteria for averaging buffer widths typically require a minimum buffer width (either a designated width or a percentage of the standard buffer width) and documentation to ensure that the averaging of the buffer will improve, or at least, not impair overall buffer functions. Ideally, buffer widths should be narrowed in an area where it will cause the least disturbance and widened in an area where it will benefit the wetland the most.

8.3.8.4 Uses Within Buffers

Another critical issue that buffer regulations need to address is the type of uses that are allowed within buffers. Generally, buffers should be maintained in vegetation. However, uses that could be considered are some stormwater treatment facilities (e.g., bioswales) or trails to provide for some form of recreational use. In addition, over time, residents adjacent to the buffer might want to use it for some activity. Thus, it is essential that buffer regulations address which uses are allowed in buffers.

Generally, any use that results in the creation of impervious areas, clearing of vegetation, or compaction of soils will be incompatible with buffer functions. Typically, buffers need to be densely vegetated with appropriate native vegetation to perform water quality and habitat-related functions. In most cases, this requirement precludes any human uses of the buffer. However, it may be necessary in some situations to use the outer area of the buffer for initial treatment of surface water runoff, via the construction of biofiltration swales or water-spreading devices to ensure sheet flow.

In other situations, it may be desirable to allow some focused use of the buffer for educational and recreational activities and to prevent widespread disturbance of the buffer. If it appears inevitable that adjacent residents will use the buffer to gain access to a wetland for aesthetic or recreational enjoyment, then it may be preferable to concentrate that use in a smaller area and minimize disturbance of the soil, vegetation, and habitat by

constructing trails, viewing platforms, or similar facilities. Additionally, providing some educational or recreational developments in buffers may enhance the general public's understanding and appreciation of wetlands and their functions and values.

Many regulations include criteria for evaluating proposals for use of buffers. These criteria typically include general language about prohibited uses but allow for variances if certain conditions are met. Care should be taken to ensure that low-impact trails are not later upgraded to paved trails that encourage activities with greater impacts. Construction of trails can allow greater access for pets to the wetland or wetland buffer and increase predation on fish and wildlife species. Regulations should minimize the impacts from trails and interpretive facilities to the extent practicable.

8.3.8.5 Enhancement and Restoration of Buffer Areas

Frequently, upland areas adjacent to wetlands have been altered by previous land-use practices. In many cases, the vegetation has been cleared or significantly degraded and the soil has been disturbed. Also, it is not uncommon to find that the existing buffer area is composed of non-native vegetation. In these situations, simply "protecting" a buffer with a set width may fail to provide the necessary characteristics to protect a wetland's functions. It is usually desirable, therefore, to restore the buffer to a more naturally vegetated condition.

In other cases, a buffer area may be in relatively good condition but still be sparsely vegetated with trees and shrubs. It may be desirable in this case to improve the screening and habitat value of the buffer by planting additional trees and shrubs or other vegetation appropriate to the ecological setting.

Buffer regulations should be designed to ensure that buffers provide adequate protection of wetland functions. Standard buffer widths should be set based on an assumption that the buffer is well vegetated. In cases where the buffer is not well vegetated, it is necessary to either increase the buffer width or require that the standard buffer width be revegetated. Generally, a well-vegetated buffer will function substantially better than a poorly vegetated buffer. Regulations can essentially give the applicant the option of revegetating the existing buffer in order to have the standard width or foregoing buffer restoration and providing a wider but poorly vegetated buffer.

Requirements for re-vegetating buffers should specify that the buffer be vegetated to a condition that is comparable to an undisturbed plant community in the ecoregion. Buffer enhancement and restoration requires the same diligence as wetland enhancement and restoration and requires monitoring and follow-up to ensure success.

8.3.8.6 Best Management Practices to Enhance or Ensure Effective Functions of Buffers

Water Quality Protection

A buffer's effectiveness at improving water quality is largely a factor of how polluted water travels across and through the buffer. The scientific literature has many references to pretreatment practices that enhance a buffer's effectiveness at removing pollutants, thereby reducing the width of buffer necessary.

In areas with agricultural or silvicultural land uses, the primary pollutants of concern are sediments, nutrients, and pesticides. Narrow (15- to 30-foot-wide) grass filter strips have been shown to be effective at removing coarse sediments and adsorbed pollutants as well as helping encourage sheetflow and infiltration of surface runoff, thus enhancing a buffer's effectiveness at removing remaining pollutants. Therefore, requiring or encouraging the construction of a narrow grass filter strip between agricultural or silvicultural areas and wetlands and their buffers is strongly advised.

In urban areas, the pollutants of concern are primarily sediments and metals from roads, parking lots, and construction sites. Adequate treatment of stormwater runoff is critical to remove most of the pollutants and to reduce peak flows prior to discharge to a wetland or its buffer (see below for more discussion of stormwater). To encourage sheetflow and infiltration, stormwater should be dispersed through a shallow infiltration trench at the outer edge of the buffer (i.e., farthest from the wetland).

In residential areas, the pollutants of concern include sediments, metals, nutrients, and pesticides (from lawns). A combination of appropriate stormwater treatment and the use of a grass filter strip or grassy swale is recommended to pretreat and disperse surface runoff prior to introduction into a buffer.

In rural residential areas, the primary concern is pollutants such as nutrients and fecal coliform from animals. Many hobby farms in rural areas house livestock that should be kept out of wetlands and their buffers.

Stormwater Management

In addition to the introduction of pollutants, development adjacent to or upgradient from a wetland can alter the quantity and timing of surface water and/or groundwater inputs to the wetland. Considerable research has documented the adverse impacts from changes in wetland hydroperiod. The scientific literature also shows that upland buffers around wetlands do little to ameliorate these impacts except in wetlands with small contributing basins. (See Chapter 4 in Volume 1 for further discussion.)

Thus, it is imperative that adequate stormwater management practices be applied to any project adjacent to or upgradient from a wetland. This includes such practices as the construction of settling/detention facilities as well as treatment with a grassy swale. Inadequately detained and treated stormwater will overwhelm a buffer's ability to filter and treat pollutants. Direct surface discharges to buffers usually result in surface flow

that is channeled, which significantly reduces pollutant removal and can erode buffers. (Refer to Chapter 3 in Volume 1 for additional information on disturbances caused by urbanization.)

Wildlife Habitat

The two primary actions that can be taken to reduce impacts to wildlife habitat are to 1) ensure that the wetland and its buffer are connected to other habitat areas, and 2) reduce the intrusion of noise, light, people, and pets.

Ensuring connectivity is usually an issue of site design. Some wetlands are already isolated from other habitat areas, and it will not be possible to provide connectivity. On sites where wetlands are currently connected to other habitat areas, it is important to maintain that connectivity through corridors. While the scientific literature indicates that wildlife travel corridors should be as wide as 500 feet, it may be beneficial to provide a corridor of any size. Generally, corridors of less than 100 feet will only provide the cover needed for small mammals and less-sensitive birds.

Local wildlife experts should be consulted to determine the appropriate corridor design for a given site. Buffer averaging can be a useful tool to help ensure connectivity with adjacent habitat areas without unduly burdening the landowner.

Reducing the intrusion of noise, light, people, and pets can be accomplished in many ways. Buffers vegetated with dense trees and shrubs are effective at reducing intrusion of noise and light. Additionally, projects can be designed to reduce noise and light intrusion by locating noisy areas such as parking lots, playgrounds, and loading docks away from the edge of the buffer. Lighting can be designed and located so it points away from the wetland and its buffer. Fences or berms can be constructed to block noise and light. Fences can also be used to limit human and pet intrusion. Dense shrubs, particularly those with thorns, can be planted along the edge of a development to block noise and light and limit intrusion.

With forethought and careful planning, projects can be designed to reduce impacts to wildlife habitat. When combined with adequately vegetated buffers of sufficient width, these measures can help ensure that disturbance to wildlife use of a wetland is minimized.

8.3.8.7 Issues in Managing Buffers

Many steps need to be considered to ensure that, once established, buffers continue to provide the functions for which they were protected. These steps frequently are overlooked or given scant attention by local governments, resulting in the degradation of buffers over time.

Ownership of the Buffer

The issue of who owns the area included within a buffer is an important one. There are basically two options:

- The buffer area can be included in a separate tract or lot and held in common ownership by a homeowners association, agency, or non-profit organization
- The buffer can be included in lots owned by adjacent landowners

The second option is often pursued by a developer who wants to divide the buffer among individual lots in order to achieve a required minimum lot size. However, a study by Cooke (in Castelle et al. 1992) of buffer areas in two counties in western Washington showed that buffers that were owned by many different lot owners were more likely to be degraded over time. Even with easement language on each lot owner's deed specifying the buffer protection provisions, owners tend to clear buffer vegetation over time to expand lawns, build storage sheds, or serve other uses.

If the buffer area is not held in some kind of common ownership, it is much more difficult to take enforcement action against those landowners who encroach upon its boundaries. Therefore, when feasible, wetlands and their buffer areas should be placed in a separate, non-buildable tract that is owned and maintained by an organization that is dedicated to protecting the buffer. The boundaries of the tract should be clearly marked to help prevent unintentional encroachments.

Buffer Delineation, Recording, and Signage

Clearly delineating and marking a buffer area helps ensure that it is not degraded over time. Following project approval, and prior to site construction, the buffer should be measured, recorded on applicable legal documents, and clearly marked on the ground. During the construction phase, constructing a temporary sediment fence or "clearing limits" fence helps to ensure that the boundary is seen by equipment operators and that the wetland and buffer are protected from erosion during construction. Following construction, a fence may still be desirable to demarcate the boundary and to limit human and pet access and reduce the intrusion of noise and light.

Placement of signs along the buffer boundary is important for two reasons: to help mark the boundary, and to help educate landowners about the purpose and value of protecting buffer areas. In areas with high potential for human intrusion and degradation of the buffer, more extensive signage explaining the value of the buffer may be necessary to develop support for protecting the buffer. In addition to signs, brochures can be developed and distributed to adjacent landowners to explain the reasons why buffers and wetlands are protected and what human activities are allowed. Typically, applicants are responsible for developing and constructing fences and signs and for distributing educational materials. However, local jurisdictions can develop standards for fences, signs, and educational materials to ensure consistency and effectiveness. Maintenance of fences and signs is typically the responsibility of the adjacent landowner or a homeowners association, if applicable, or lies with the local jurisdiction.

Maintenance of Buffers

In cases where enhancement or restoration of a buffer is required, monitoring and maintaining the buffer area is essential. A monitoring/maintenance program should include evaluation of the success of plantings and provide for contingency measures if vegetation survival standards are not met. Responsibility for this is usually borne by the developer or landowner. It is also important to monitor buffer areas when human use is allowed or expected. Adverse effects of human access such as vegetation trampling, littering, and soil compaction or erosion should be monitored and corrected if found. Local jurisdictions can develop and implement a buffer maintenance and monitoring program but few have done so. Alternatively, applicants can be required to monitor and maintain buffers and submit regular reports to the local jurisdiction.

Enforcement

Simply designating and marking the boundaries of buffer areas is not sufficient to protect buffers in all cases. Regular observation of buffer areas is critical to determine whether vegetation and soils are being damaged and to ensure that adjacent development does not encroach on the buffer over time. Where illegal activities occur, enforcement actions to restore the buffer may be necessary. Local jurisdictions should establish a program to observe the buffer over time and take enforcement actions when necessary, similar to programs for private stormwater or wastewater facilities.

8.3.8.8 Buffers in Urban Areas

A frequent concern about buffers is their applicability to urban and urbanizing areas. The concerns generally fall into two categories: 1) the science on buffers comes largely from agricultural and forestry settings and is perceived to be irrelevant to urban areas; and 2) the need to maximize density of development in urban areas is in direct conflict with the protection of large upland areas around wetlands (and streams).

The concern over the relevancy of the literature on buffers to urban areas is largely unfounded. While most of the studies of buffer effectiveness occur in non-urban settings, the principles are the same. Buffers do not function any differently in urban settings than in rural settings. The same processes of sediment, nutrient, and toxics removal operate similarly in urban areas as they do in rural settings. However, a good stormwater management program can reduce the need for buffers to perform filtration functions, with the exception of lawns and landscaped areas which drain into wetlands rather than into stormwater collection areas.

The role of buffers in providing needed upland habitat for wetland species and in screening adjacent noise and light is also performed similarly. In fact, a case can be made that buffers in urban areas are even more important from a habitat standpoint because there is little other upland habitat available. The factors that may be different in urban areas are that urban wetlands may perform some functions at a lower level because of degradation, and the range of wildlife species utilizing urban wetlands may be smaller. However, remaining wetlands (and adjacent upland areas) in urban areas may, in fact,

function as habitat islands and be critical to many species. Generally, the protection of wildlife habitat functions of wetlands requires larger buffers than protection of water quality functions, particularly when state-of-the-art stormwater management is employed.

However, the best way to address the issue of buffers in urban areas is to conduct a landscape analysis and develop a subarea plan that identifies, prioritizes, and protects the most important wetland, riparian, and upland habitats (see Chapters 5 through 7 of this volume for additional discussion). Maintaining and restoring connections between wetland, riparian, and upland habitats is key to protecting wildlife. A landscape analysis can help identify existing connections that should be protected as well as areas where connectivity can be restored. Combined with standards for low impact development and state-of-the-art stormwater management, this kind of approach could result in smaller buffers around the other critical areas that are not providing vital habitat. The studies should always be confirmed on the ground during project review.

The issue of balancing wetland protection with competing mandates in the GMA is a legitimate one that can be addressed in a number of ways. A buildable lands survey with a good wetlands inventory can provide important information on the actual conflicts that may exist (rather than a perceived conflict). Provisions to allow density trading from buffers to adjacent or nearby developable lands can help.

8.4 Monitoring the Effectiveness of the Regulatory Component of a Protection Program

A local government should be able to track the effects of decisions made in the implementation of its critical areas ordinance and produce regular status reports for the public to review. This is an important step to demonstrate that the goals and requirements of the GMA are being met. The following are examples of questions that should be answered:

- How many wetlands have been affected by permit decisions?
- How many acres have been filled?
- How much and what type of mitigation was required?
- How many requests for buffer reductions have been granted? (Associated questions include: how many projects included buffer increases, how narrow/wide was the buffer reduction/increase, how many acres of buffers were involved in buffer reduction/increases, and was off-site mitigation required as part of the buffer reduction?)
- How many projects included provisions for wildlife corridors to connect adjacent wetlands? (An associated question is: how many acres of upland buffers were affected by these buffer considerations?)

- How well have the mitigation projects succeeded in replacing wetland acreage and function?
- How many variances have been issued? (Associated questions include: how many exemptions have been granted, and how many violations have occurred?)
- How many emergency waivers have been issued? (An associated question is how many required after-the-fact mitigation?)
- How much non-compensatory restoration is being done?
- How many acres of impacts have been avoided, by basin?

Without the collection of these data, a local government cannot evaluate how well it is doing in moving toward a goal of "no net loss goal" for its regulation. Furthermore, these data are an integral part of a local government's adaptive management approach because they allow decision-makers to improve the regulations based on real data.

Monitoring does not have to be complicated but should be linked to the goals established for the regulations (discussed in Section 8.2). A regulation with rigid requirements will not require as much data collection as one that relies on case-by-case flexible implementation. Flexible programs by design represent a higher risk to wetlands because case-by-case decision-making can lead to greater cumulative effects than more rigid regulatory programs. (See Balancing Predictability with Flexibility in Section 8.2.1). Many of these data can be collected as part of follow-up work for permit compliance.

This chapter has not outlined the minimum features to include for monitoring because they are entirely dependent on what language is adopted in code. See Chapter 12 of this volume for additional information on monitoring and adaptive management.

Chapter 9

Prescribing Solutions: Non-Regulatory Tools

9.1 Introduction

Non-regulatory tools, discussed in this chapter, provide important solutions to protecting and managing wetlands, and they comprise a key component of any wetland protection program. Developing non-regulatory approaches is a part of Step 2, Prescribing Solutions, in the four-step framework discussed in this volume (Figure 9-1).

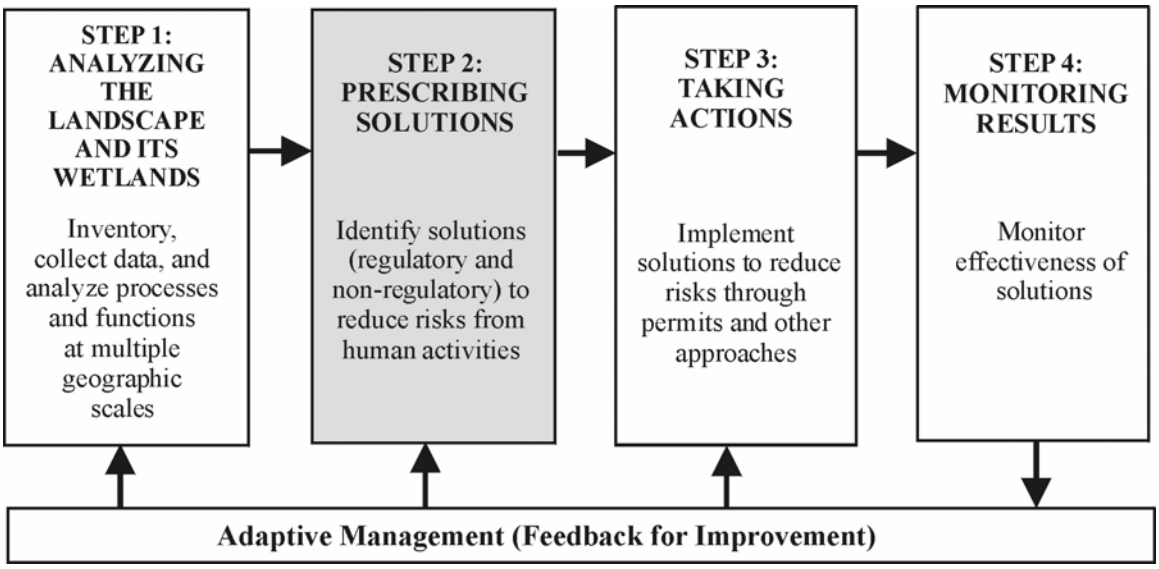

Figure 9-1. Developing non-regulatory tools is part of Step 2 in the four-step framework for protecting and managing wetlands (shaded box).

Non-regulatory activities are voluntary in nature and complement land-use regulations used to protect and manage wetlands. As mentioned in Chapter 8, regulations alone cannot adequately protect wetlands. For example, regulatory tools, such as buffers and compensatory mitigation, establish standards for protecting and managing resources when a land-use action is proposed on a specific site. Non-regulatory approaches, including preservation, conservation, restoration, and incentives, can be used on both a site-specific basis and can be applied to an entire management area.

In addition, non-regulatory activities, as a part of a wetland protection program, are important because they:

- Reduce risk of loss and/or degradation of critical wetlands (*Critical* in this context means those wetlands that provide essential contributions to the landscape or to society)

- Provide options for landowners and governments in the early stages of making decisions about the conservation of landscape processes and wetlands (see Section 9.2 for a description of "conservation")
- Can address large areas of the landscape and thus be effective in protecting landscape processes and wetland functions
- Meet the needs of those landowners who prefer a voluntary option
- Provide a proactive approach to improve landscape conditions that incorporates willing landowner and community participation
- Help to achieve no net loss and make eventual gains in wetland function and acreage
- Have financial and tax benefits

Therefore, the goal of protecting wetland functions and values, and associated landscape processes, is best accomplished when using wide range of activities: An effective protection program needs to include both regulatory and non-regulatory components.

Developing and incorporating non-regulatory tools can occur at any stage of a jurisdiction's planning process. However, non-regulatory efforts will be most effective if they are integrated in the early stages of planning; for example, during the formation of a Green Infrastructure plan (Chapter 6). During these early stages, the information from a landscape analysis (Chapter 5) can be used to help the jurisdiction assess options for maintaining landscape processes into the future and to decide which options provide the most desirable outcome. The non-regulatory component of a wetland protection program can then be used as a means to help achieve this outcome.

9.2 Three Categories of Non-Regulatory Actions to Consider

Non-regulatory actions fall into three general categories:

- **Preservation** provides a way to set lands aside so that they are not actively used for human activities
- **Conservation** allows for human activities but limits their impacts by applying best management practices and other measures to protect resource functions
- **Restoration** serves to return the land to a condition in which it performs functions and contributes to landscape processes in a manner similar to past conditions. For wetlands, the key step is re-establishing the appropriate water regime

Preservation, conservation, and restoration are actions that are used in both regulatory and non-regulatory contexts. In the regulatory context, these terms may represent actions that are more limited in scope. For example, preservation may be defined narrowly. As described in the recent regulatory guidance by Ecology and the U.S. Army Corps of Engineers (April 2004), preservation can be used only under specific conditions such as preserving a wetland that is under immediate threat. Comparatively, in a non-regulatory context, preservation can be applied whenever a particular wetland is considered of high importance thus warranting permanent protection to remove any future threats.

As previously mentioned, conducting a landscape analysis (see Chapter 5) is very helpful in determining how each of these types of non-regulatory actions can supplement regulatory tools to ensure that landscape processes are maintained. Generally, all three may be desirable for maintaining landscape processes. However, some jurisdictions may find that only one or two of these actions will be the primary focus, while others may incorporate all three.

Each of these non-regulatory actions can be used at various locations within a jurisdiction, and a landscape analysis clarifies which non-regulatory action is most relevant to respective locations. For example, a particular sub-basin may be dominated by agriculture and have water quality problems but have a high potential for water quality improvement if wetlands were restored. In this case, the focus of non-regulatory efforts could be improving *conservation* through application of best management practices in agricultural areas while initiating *restoration* of wetlands where landowners are willing. In another sub-basin with high growth rates, the need might be to use *preservation* of wetlands that provide high habitat functions at the fringe of an urban growth area.

Understanding the landscape processes therefore helps with the design of non-regulatory actions and implementation through non-regulatory tools. Appropriate tools can then be applied broadly throughout the entire management area or selectively in the areas in which they are most relevant.

A brief overview of preservation, conservation, and restoration in the non-regulatory context is provided below. The specific tools that can be used to implement these non-regulatory actions are discussed in more detail later in this chapter and in the chapter on implementation (see Chapter 11).

9.2.1 Preservation

In their paper on *Conservation of Biodiversity in a World of Use*, Redford and Richter (1999) state:

> *(1) different degrees of human use or alteration result in differential conservation of biodiversity components, (2) some components and attributes of biodiversity are more sensitive to human use than others, and (3) only extremely limited use or virtually no alteration will protect all components.*

Thus, a key role for preservation is to permanently protect those areas that are so highly sensitive to use, so rare or irreplaceable, or so critical to landscape processes that their degradation or loss cannot be afforded.

Preservation employs the permanent protection of land through either:

- Full-fee, title ownership of all property rights
- Partial ownership of the development and/or use rights to the land through a conservation easement

Conservation easements serve to protect the land into the future (often in perpetuity) by restricting the property deed with conditions for preservation. A "holder" of the conservation easement (such as a land trust) is designated to enforce the terms of the easement through time. Short of full-fee purchase, conservation easements are the strongest legal protections available for land preservation.

9.2.2 Conservation

As previously mentioned, conservation allows for the active use of the land while maintaining landscape processes over time. Conservation applies to areas used for resource production. For example, owners of land used for agriculture and forestry are encouraged to apply best management practices such as riparian and wetland buffers.

Conservation also applies to urbanizing areas where changes in land use might adversely impact a resource. Conservation of wetlands is a concern in urbanizing settings where adjacent use by humans affects wetlands and buffers. Improved management practices on the part of homeowner associations, private landowners, and land developers can help to reduce impacts. Education and outreach are vital in promoting the use of appropriate conservation tools.

9.2.3 Restoration

Restoration provides a method for recovering landscape processes and wetland functions that have been lost or degraded. While mitigation actions in a regulatory context compensate for the loss of acreage or functions as a result of a current development activity, they are not designed to recover wetland acreage or functions that have been lost in the past. However, voluntary (non-compensatory) restoration can restore acreage and functions lost as a result of past land uses.

Some types of wetlands have been more altered than others due to the relative ease of draining and converting them to other uses, as well as other factors. The net result has been a homogenization (i.e., reduction in diversity) of the remaining wetlands and a shift in the relative proportion of habitat types and functions performed (see Chapter 4 in Volume 1). Wetlands have also been affected in terms of their distance from each other, the connectivity of habitat between them, and their location, distribution, and position in the landscape. This affects the dispersal of animals and plants between wetlands and how wetlands affect water quality, flood attenuation, and hydrologic processes (Bedford 1999,

citing Brinson 1993). These and other factors need to be considered as part of non-regulatory, wetland restoration efforts.

9.3 Fiscal Benefits of Using Non-Regulatory Tools

One of the most important considerations in using non-regulatory actions and tools in a wetland protection program is fiscal savings. Fiscal savings fall into two categories: 1) the efficiencies resulting from the maintenance of services performed by "green infrastructure", and 2) the savings gained by implementing actions at the optimal geographic location to effectively address problems in the landscape or watershed.

As discussed in Chapter 6, landscapes and their wetlands provide an array of green infrastructure services (e.g., flood attenuation, improvement in water quality, the recharge of water, etc.) Studies have indicated that protecting existing green infrastructure, instead of having to engineer and build "grey infrastructure" to replace the green infrastructure, actually saves money (see Chapter 6). For example, despite the common perception that non-regulatory programs are too expensive, money spent to purchase land for permanent preservation and thus protect its functions and services can result in a significant financial savings over the long term. Therefore, when considering the goals of non-regulatory efforts, the jurisdiction should understand these financial implications.

Cost efficiencies are increased when the non-regulatory actions and the funds to implement such actions are targeted to the ideal or optimal locations, such as "problem" areas within sub-basins or watersheds which have been identified using a landscape analysis. (The analysis can also help identify the appropriate non-regulatory actions to use to help correct the problems.) Thus, targeting the right action in the right place is a wise and effective use of funds. Also, prioritizing which locations need attention first helps to minimize further loss of landscape processes, thereby retaining existing green infrastructure.

An active education initiative that includes fiscal benefits is essential. As previously mentioned, it is important that citizens and political leaders are aware of fiscal benefits. They should understand that short-term costs to preserve land, and any loss of tax revenues on that land, will be offset over the long term by savings from the functions and services the land provides. In addition, it is also important to know that the cost of providing built infrastructure can out pace tax revenues generated by new development. Conveying this information to local leaders and citizens increases understanding and promotes support for non-regulatory programs.

Jurisdictions in several parts of the country have conducted fiscal analyses to document the cost savings that a non-regulatory approach can provide. Further information on these savings can be found in Chapter 6 and Appendix 6-A.

9.4 Important Considerations When Incorporating Non-Regulatory Tools

When establishing the non-regulatory components of a wetland program, developing the overall vision and the goals to be accomplished should be the first step. A clear foundation on which to build the non-regulatory effort will already have been laid if a Green Infrastructure plan has been prepared or the community has engaged in an Alternative Futures analysis (see Chapter 6). From there, the identification of the locations and type of actions (conservation, preservation, and restoration) for specific sites can readily be determined.

In addition to the vision and goals, several practical considerations must be addressed to initiate the non-regulatory components. The following are some essential parts of an effective non-regulatory effort:

- Staffing (e.g., coordinator, support staff, staff for site management, etc.)
- Identifying, mapping, and prioritizing where non-regulatory tools will be applied
- Creating partnerships with organization, government agencies, and others to help sponsor local projects
- Identifying a recipient to hold and manage land
- Obtaining funding for local actions
- Providing incentives to encourage participation by landowners
- Educating and involving the public and providing technical outreach to the public and landowners
- Monitoring project sites and the overall success of the non-regulatory actions

Most of these are discussed in the implementation portion of this document (see Chapter 11). However, an overview of key funding mechanisms and landowner incentives are provided in Section 9.4.1 in this chapter.

For more details on funding and incentives, as well as complete coverage of landowner conservation tools, please refer to the *Exploring Wetlands Stewardship Guide: A Reference Guide for Assisting Washington Landowners and Communities* (Rubey 2004). http://www.ecy.wa.gov/biblio/96120.html or http://www.ecy.wa.gov/pubs/96120.pdf

9.4.1 Funding Mechanisms

Purchasing land to preserve it, whether in *full-fee title* or *less-than-fee development rights*, requires some form of local revenue. Full-fee title (also *fee-simple, full purchase, or full-interest*) is the acquisition of all rights to a parcel of land, including development rights, mining rights, timber rights, etc. *Less-than-fee title* (or *partial-interest purchase*) is the acquisition of some of the rights to a parcel of land but not all (for example, the acquisition of development rights only).

Common forms of financing for preservation (and other conservation measures) include property taxes, sales or use taxes, real estate transfer taxes, impact fees, special assessment districts, general obligation bonds, and revenue bonds. The ability to raise local revenue for conservation allows the money to be used as a match to obtain additional funds through state or federal grants, thus enhancing the potential for funding local conservation.

In *Local Greenprinting for Growth*, the Trust for Public Lands and National Association of County Officials (2002) provide the following table which summarizes common sources of conservation financing with a list of pros and cons for each.

Table 9-1. Common sources of financing for conservation.

Financing Source	Definition	Pros	Cons
Property tax	Tax on real property paid by commercial and residential property owners	Steady source of revenue Relatively easily administered Tax burden is distributed Small increases create substantial funding Popular with voters when focuses on compelling needs of land conservation	Competition for other public uses Overall concern among taxpayers about higher rates
Sales & use tax	Tax in sales of goods and services	Relatively easy to administer Low reporting costs Can generate large sums, even at small tax levels May be paid in part by out-of-town visitors Can tap into tourism profits generated by open space amenities May include exemptions such as food & medicine	Revenues can drop when economy slows Considered regressive

Financing Source	Definition	Pros	Cons
Real estate tax	Tax on the sales of property paid by either the buyer or seller at time of transfer	Funds can be substantial Connection between taxing new development and protecting open space	Initial opposition from real estate/development interests can make passage difficult Less predictable revenue stream
Impact fees	One-time fee paid by developer to offset costs of infrastructure needed for new development	Connection between taxing new development and protecting open space	Parks and open space projects might require direct link to new development
Special assessment district	Special tax district for area that benefits from an open space area	Users finance acquisition and management Predictable revenue stream Accountability in government spending Sense of ownership of and responsibility for area parks and services Can establish in small increments May be able to set own election date and process	Possibly time consuming to implement Overall concern among taxpayers about high rates
General obligation bond	Loan taken out by a city or county against the value of the taxable property	Allows for immediate purchase of open space, locking in land at current prices Distributes the cost of acquisition over time	Extra costs associated with the interest accrued through borrowing Voter approval required, sometimes by supermajority levels
Revenue bond	Loan paid from proceeds of a tax levied for the use of a specific public project or with proceeds of fees charged to those who use the financed facility	Not constrained by the debt ceilings of general obligation bonds Voter approval rarely required	More expensive than general obligation bonds
Source: Trust for Public Lands and National Association of County Officials (2002).			

9.4.1.1 Common Forms of Conservation Revenue in Washington

In Washington, one of the most common forms of conservation revenue comes from the Conservation Futures Levy. RCW 84.34.200 and RCW 84.34.230 established the authorization for any Washington county to administer a real property tax in the amount of $0.0625 per $1000 of assessed valuation. This provision for conservation fund-raising at the local level is quite unique in the country and presents an opportunity for local communities to acquire and preserve wetlands and other areas that provide green infrastructure services. However, it is currently used by only a third of the counties in the state. Those counties that are using it have been quite successful, over the years, in preserving important lands within their communities.

General obligation bonds and impact fees have also been frequently used by local jurisdictions in Washington for conservation purposes. General obligation bonds are generated by local governments, and the revenue can be used to finance conservation activities, with the principle repaid over time. Impact fees are charged when a site is developed, and the fees can be dedicated to finance conservation of open space to compensate for losses caused by the development.

9.4.1.2 Land Banking

Land banking is a tool that raises funds from land acquisition by placing a tax on real estate sales within the jurisdiction. It was first initiated in Massachusetts in 1984. In 1990, Washington State authorized a real estate excise tax under RCW 82.46.070 for the establishment of land banks. This authority allows counties to impose a property transfer tax where tax proceeds are used exclusively for fee-simple or less-than-fee acquisition and/or maintenance of conservation areas. Initiated either by resolution of the county legislators or by the public through a petition, the excise tax is approved by citizen vote.

Only one Washington jurisdiction, San Juan County, has established this form of tax revenue. The San Juan County Land Bank, established in 1990, has successfully completed conservation easements on 17,000 acres and fee purchase on approximately 900 acres. To date, they have received between $18 million and $19 million in revenue. After its original authorization period of 12 years, the program was extended following active campaigning by local real estate agents. The land bank was reauthorized with a 74% approval by county residents (Shaffer, San Juan County Land Bank, personal communication 2003).

Communities in Cape Cod are also moving toward establishing land banks to address growth while protecting their resources. This is discussed in a paper by Cummiskey (2001) in which the author describes the development of a land bank in Cape Cod during the late 1990s. Cummiskey states that despite the existence of numerous tools such as building restrictions, zoning bylaws, subdivision regulations, and historic district designations, accelerating development continued to threaten shorelines and other resources. This necessitated the addition of other management tools to protect the

lifestyle and natural qualities of Cape Cod. The author points out that more cities and towns in Massachusetts and other states are considering land banks as growth management tools to address coastal development, as well as urban, suburban, and rural sprawl.

9.4.2 Landowner Incentives

It is important to have a broad range of tools available to address the needs of each individual landowner. Tools that incorporate some form of market-based incentive help to motivate conservation. With this in mind, local governments can conduct full-interest and partial-interest land purchases (conservation easements), and/or they can establish tax-based incentives and incentive zoning with tradable development rights and cluster or higher density alternatives. As previously mentioned, it is best to institute these tools early in the planning process to allow for their optimum use. A few are discussed in this section as well as Section 9.4.3, Incentive Zoning and Regulation.

9.4.2.1 Incentive-based Tools: Open Space Current Use Taxation

"Land taxes often act as a disincentive to landowners wishing to conserve natural areas" (Edwards 1994). In *Developing America's Natural Areas Market*, Edwards states that government can assist in conservation by removing existing disincentives to private protection of land and by assisting in developing a market for areas that are maintained as "natural areas" rather than relying on private conservation programs alone.

Washington's Open Space Current Use Taxation (CUT) Program (RCW 84.34) removes such disincentives. It allows local governments to offer landowners voluntary enrollment of undeveloped property in their county's program. The open space element of the CUT program provides reductions in property tax for the conservation of features of natural resources considered of value to the community at large. The optional Public Benefit Rating System (PBRS) allows the local jurisdiction to identify which "features" of natural resources that will be considered in the program, targeting those that are deemed most beneficial to the community. In the PBRS, the specific criteria related to these features are clearly defined and are used to score a property. These criteria assess its eligibility for enrollment in the CUT program and determine the level of tax reduction. The PBRS therefore allows flexibility to shape the CUT Program to protect landscape processes by targeting features that help maintain those processes.

Applying the Public Benefit Rating System as a Watershed Action Tool (Rubey 1999) provides guidance for local jurisdictions who wish to use the PBRS more strategically. The guidance includes specific criteria to identify properties containing natural resource features that will help ameliorate water quality problems, flooding, habitat loss, etc.

Using the PBRS criteria can even be tailored to address the needs of different sub-basins within the overall jurisdiction. A tailored PBRS is an ideal tool when implementing Alternative Futures or Green Infrastructure plans.

9.4.2.2 Other Incentive-Based Tools

There are other incentive-based options, listed below and discussed briefly, from which landowners can benefit by protecting and enhancing ecosystems including wetlands:

- Transferring property title with compensation
- Retaining ownership and managing the property
- Conservation in the context of development (see Section 9.4.3)

The reader is referred to *Exploring Wetlands Stewardship, A Reference Guide for Assisting Washington Landowners and Communities* (Rubey 2004) for a detailed discussion of these options, as well as the other conservation and stewardship issues. For example, Rubey (2004) covers the grant programs available to assist implementing preservation and restoration projects. The document also includes a complete listing of state and federal programs, with many local programs, as a resource to correspond non-regulatory wetland projects with potential funding.

Transferring Property Title with Compensation

Transfer of property title <u>with</u> compensation is used in the context of funding mechanisms for the purchase of property title. There are numerous non-regulatory tools available which can be employed to bring a purchase of land to closure. These include bargain sales, installment sales, land exchanges, options to buy, reserved life estate, right of first refusal, self finance, and tax deferred exchange. *Transfers of title <u>without</u> compensation* would include different forms of donations such as bequest, leaseback, outright, and reserved life estate or remainder interest.

Retaining Ownership and Managing the Property

A landowner can retain ownership and management of the property while providing conservation through a *conservation lease.* When purchase of property and/or a conservation easement (which provide permanent protection) are not available or acceptable to a private landowner, another less-permanent option is a conservation lease (also called a *resource conservation agreement*). The conservation lease offers tax relief or a conservation management payment as the incentive for conservation.

Conservation leases are often a preferred approach for agricultural or timber landowners. Main et al. (1999) point out that the system of taxation in the United States discourages agricultural landowners letting lands remain fallow when they are marginal for agriculture (e.g., wetlands), thus fueling the conversion of wetland habitats and resulting in loss or fragmentation. A conservation lease can offer some compensation to these landowners for conserving lands, rather than using them as marginal farmed lands.

Other options for retaining ownership with conservation are mutual covenants, open space current use classification, and undivided interest. As mentioned previously, more details on all of these tools are provided in *Exploring Wetlands Stewardship, A Reference Guide for Assisting Washington Landowners and Communities* (Rubey 2004).

9.4.3 Incentive Zoning and Regulation

There are also some tools that provide conservation incentives to landowners within the context of regulating development. *Incentive zoning* operates within the regulatory component of an existing protection program to influence development toward preservation of open space. One example is clustered development. Clustered development requires that development be placed on a small portion of the parcel, thereby retaining the balance as open space. Incentives for denser development of up to 20% have been allowed in some communities where a larger number of lots than usually allowed are exchanged for dedicating additional open space (Smart Growth Network 2002).

The transfer of development rights (TDR) is also frequently considered. Basically, TDR moves the allowed rights of development from a less desirable site (with higher resource functions or values) to a less sensitive site (more suited to development). A strong real estate market is necessary to fuel the transfer, and very abundant and uncontroversial sites for the transfer (receiving sites) must exist. Also, the zone proposed for preservation must have comparatively lower activity in regard to the real estate market. For example, McGilvray et al. (1985) found that saltmarsh lagoons in coastal communities were hard to preserve using TDR because of the high property values associated with ocean views.

Brabec and Smith (2002) studied TDR, purchase of development rights (PDR), and cluster development in the eastern United States in regard to fragmentation in agricultural lands. They found that TDR and PDR worked best for maintaining viable agricultural practices and preventing isolation and reduction in size. Because the area they studied had a strong transfer market, the TDR tool performed well. The TDR resulted in the aggregation of 91% of the parcels into protected areas with an average size of 465 acres. The PDR programs aggregated 75 to 88% in the various communities studied. With the cluster program, 36% of the sites were aggregated (64% isolated) and averaged only 30 acres in size.

Avoiding fragmentation is a key aspect of any conservation strategy, so this study provides valuable insights regarding the potential of these tools for wetland applications. The analysis and comparison of these three incentive-based, regulatory tools reinforces the importance of using and coordinating a variety of non-regulatory and regulatory tools to achieve optimal results (Brabec and Smith 2002).

Chapter 10

Prescribing Solutions: Characterization of Risks

10.1 Introduction

This chapter builds on previous chapters by discussing the importance of characterizing the risks that are inherent in the solutions developed in Step 2 of the framework of a wetland protection program (Figure 10-1). The scientific information available indicates that as human populations grow, we increasingly impact the environmental processes that maintain the functions of our natural resources (Dale et al. 2000). We have not yet found the ways by which we can completely eliminate impacts in the face of our growing population. Therefore, the goal for protecting and managing our natural resources, including wetlands, should be to minimize the risk to resources from our activities, thereby, also reducing cumulative impacts (Cairns 1997).

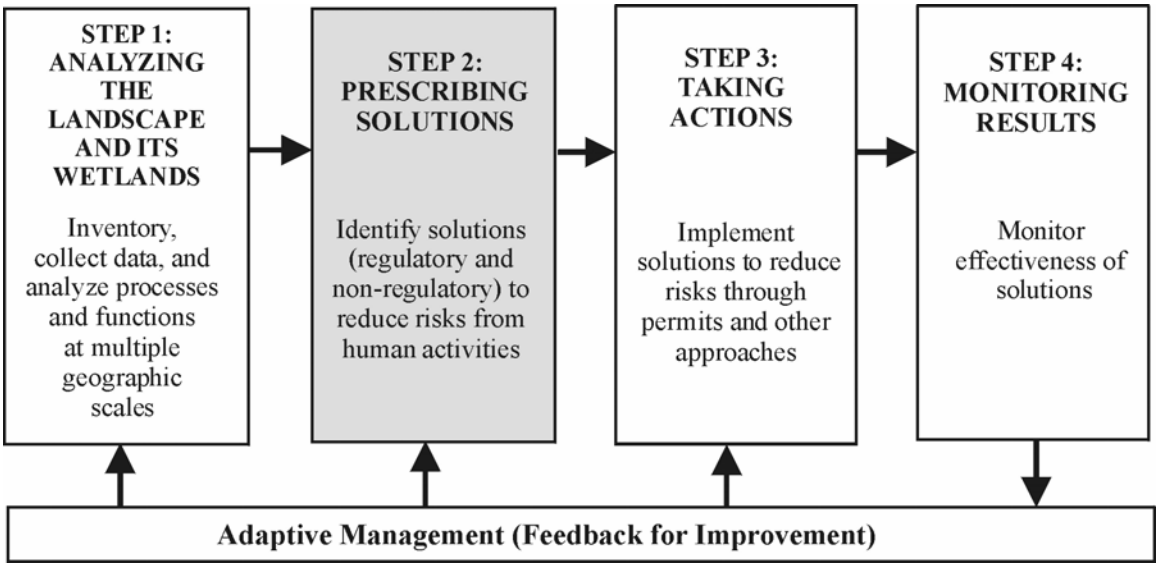

Figure 10-1. Characterizing risks is part of Step 2, Prescribing Solutions, within the four-step framework recommended for protecting and managing wetlands (shaded box).

Risks are minimized by first understanding the risks inherent in actions taken and then developing a program that minimizes those risks. The first step, developing an understanding of risks, is called a *characterization of risks* or *risk assessment.* A characterization of risks considers the impacts and benefits that result from actions that are proposed to be taken. A characterization provides a way to develop, organize, and present scientific information so that it is useful in making decisions about future land

uses. The characterization can provide a basis for comparing different options for protecting and managing wetlands, and it should enable decision-makers and the public to make more informed decisions about wetland resources.

In a characterization of risks, local jurisdictions should consider whether the plans, policies, and regulations they are developing will minimize the risk of cumulative impacts to the functions and values of natural resources including wetlands. If the risk to the wetland resource is still high with the proposed actions in place, the jurisdiction should identify additional measures that can be taken to reduce the risk.

The descriptions of impacts and benefits used for a characterization of risks may range from qualitative judgments to numeric estimates of probability. The guidance for characterizing risks described in this chapter can be applied to both qualitative and quantitative approaches. Local governments are encouraged to characterize the risks of each policy, zoning plan, regulation, exemption, incentive, restoration program, etc. based on the impacts or benefits it poses to landscape processes and the wetland resource.

For example, a regulation that represents a relatively low risk to wetlands is to set a standard 300-foot buffer around every wetland. This is not necessarily recommended because it does not take into account differences among wetlands, but it would significantly reduce the risk to wetlands from human activities in the immediate vicinity. Such a standard could be characterized as having "low risk." On another extreme, a local government may apply a 30-foot buffer around all their wetlands, which could be characterized as "high risk." The review of the literature indicates that a 30-foot buffer alone is not large enough to protect most functions of a wetland. By consistently applying a 30-foot buffer around all wetlands, the functions of wetlands in the jurisdiction will be degraded and result in cumulative impacts such as "space crowding" and "fragmentation" (see Chapter 7 in Volume 1).

There are no simple, unambiguous methods to characterize the risks of different actions that can be taken by local jurisdictions to protect wetlands. The methods are being developed and are still quite subjective. The departments of Ecology and Fish and Wildlife recommend, however, that local jurisdictions try to characterize the risks of their actions. A subjective characterization is better than none at all if the choices and decisions made are documented. The following section outlines one type of process by which the risks can be characterized and documented.

10.2 Risk and the Growth Management Act

A characterization of risks of proposed solutions for protecting and managing wetlands is not a statutory requirement of the Growth Management Act. However, the procedural guidelines (WAC 365-195) adopted by the department of Community, Trade, and Economic Development (CTED) in 2001 recommend that risks to critical areas resulting from the adoption of policies and development regulations be identified. The risks should be identified if the policies and regulations depart from the best available science

established in the record or where adequate scientific information is lacking. Following are relevant excerpts from WAC 365-195.

The following section describes the process that should be used when a local jurisdiction determines that it cannot, for some reason, include the best available science in its development policies and regulations. In these cases, the clear identification of risks to the functions and values of critical areas is essential (see bolded language below).

WAC 365-195-915 Criteria for including the best available science in developing policies and development regulations.

(1) To demonstrate that the best available science has been included in the development of critical areas policies and regulations, counties and cities should address each of the following on the record:

(a) The specific policies and development regulations adopted to protect the functions and values of the critical areas at issue.

(b) The relevant sources of best available scientific information included in the decision-making.

(c) Any nonscientific information -- including legal, social, cultural, economic, and political information -- used as a basis for critical area policies and regulations that depart from recommendations derived from the best available science. A county or city departing from science-based recommendations should:

(i) Identify the information in the record that supports its decision to depart from science-based recommendations;

(ii) Explain its rationale for departing from science-based recommendations; and

(iii) Identify potential risks to the functions and values of the critical area or areas at issue and any additional measures chosen to limit such risks. State Environmental Policy Act (SEPA) review often provides an opportunity to establish and publish the record of this assessment.

(2) Counties and cities should include the best available science in determining whether to grant applications for administrative variances and exemptions from generally applicable provisions in policies and development regulations adopted to protect the functions and values of critical areas. Counties and cities should adopt procedures and criteria to ensure that the best available science is included in every review of an application for an administrative variance or exemption.

In addition, the WAC addresses situations where there is a lack of adequate scientific information upon which to base development policies and regulations.

WAC 365-195-920 Criteria for addressing inadequate scientific information.

Where there is an absence of valid scientific information or incomplete scientific information relating to a county's or city's critical areas, leading to uncertainty about which development and land uses could lead to harm of critical areas or uncertainty about the risk to critical area function of permitting development, counties and cities should use the following approach:

(1) A "precautionary or a no-risk approach," in which development and land use activities are strictly limited until the uncertainty is sufficiently resolved; and

(2) As an interim approach, an effective adaptive management program that relies on scientific methods to evaluate how well regulatory and non-regulatory actions achieve their objectives. Management, policy, and regulatory actions are treated as experiments that are purposefully monitored and evaluated to determine whether they are effective and, if not, how they should be improved to increase their effectiveness. An adaptive management program is a formal and deliberate scientific approach to taking action and obtaining information in the face of uncertainty. To effectively implement an adaptive management program, counties and cities should be willing to:

(a) Address funding for the research component of the adaptive management program;

(b) Change course based on the results and interpretation of new information that resolves uncertainties; and

(c) Commit to the appropriate timeframe and scale necessary to reliably evaluate regulatory and non-regulatory actions affecting critical areas protection and anadromous fisheries.

10.3 A Process for Characterizing Risks

Ideally, local jurisdictions will be taking steps to protect and manage wetlands at the different geographic scales discussed in previous chapters. The goal is to reduce risks to natural resources to levels that can be considered acceptable. Please note however, that this document does not try to establish what might be considered an “acceptable risk” to the wetland resources. This has to be determined by each jurisdiction based on the laws and policies they are trying to implement and the functions and values of the resources they are trying to protect.

Whether planning is done at the scale of the management area or the site itself, the risks can be characterized by answering a series of questions about the actions being proposed:

- What disturbances or benefits will result from a proposed action (e.g., change in land use through zoning, regulations that affect how land is used, restoration plan, etc.)?
- What risks do these disturbances pose to the functions and values of wetlands?
- What measures are proposed to minimize the risks or replace the resource at risk?

10.3.1 Identifying the Environmental Disturbances or Benefits that Result from Proposed Actions

Chapter 3 in Volume 1 summarized the different types of environmental disturbances that can occur as humans modify ecosystems to meet their needs. The plans, regulations, restoration actions, etc. taken by local jurisdictions to direct and control the use of land can also be characterized in terms of the disturbances they may allow or rectify. The first step in characterizing the risk, therefore, is to identify how a specific type of land-use activity may cause an environmental disturbance or benefit.

The characterization of risks should start with a thorough list of the different actions being proposed to protect and manage wetlands (e.g., zoning categories, regulations, exemptions, ordinances, etc.). Each of these has the potential to cause an environmental disturbance by allowing certain land uses to occur or by changing the current land use to some other one.

The types of environmental disturbances identified in Volume 1 include:

- Changing the physical structure within a wetland (e.g., filling, removing vegetation, tilling soils, compacting soils)
- Changing the amount of water (increasing or decreasing the amount)
- Changing the fluctuation of water levels (frequency, amplitude, direction of flow)
- Changing the amount of sediment (increasing or decreasing the amount)
- Increasing the amount of nutrients
- Increasing the amount of toxic contaminants
- Changing the acidity (acidification)
- Increasing the concentration of salt (salinization)
- Fragmentation of habitats
- Other disturbances (noise, etc.)

For example, a jurisdiction may be revising their zoning ordinance and zone an area that was previously rural as urban to accommodate growth. The potential disturbances that may result from this action include changing the patterns of water flow, increasing the input of nutrients and toxic compounds, and causing fragmentation of habitat on the landscape. Another area may be re-zoned from low- to high-density residential. This would result in changes in the patterns of water flow, introduction of toxics from lawn care, and increase the disturbance to wildlife by introducing more predation by pets.

An example of disturbances caused by management actions at the site scale is allowing single-family residences, as an exemption, in the buffers of wetlands. Such an action

would allow disturbances such as the introduction of nutrients and toxics from lawn care and pets, and possibly a change in water regime to occur.

Table 10-1 provides an example of how the environmental disturbances and risks associated with various management actions could be summarized.

Table 10-1. An example of a table summarizing risks associated with common land-use actions.

Action	Disturbance Caused by Allowing Action	Risk of Disturbance to Wetland Functions and Values
Urban zoning in a recharge area	Change in water regime, increased surface runoff, and less infiltration	High for wetlands fed by groundwater and for those that will receive the direct runoff from paved surfaces
Permit fill of wetlands	Change in structure of wetland and loss of wetland area	High for functions within wetland
300-ft buffers for wetlands with a high habitat score	Minimal	Low
200- to 300-ft buffers for high habitat score	Will allow some disturbance of wildlife and limit upland zones suitable for amphibians	Moderate
< 200-ft buffers for high habitat score	Significant disturbance of wildlife	High

10.3.2 Identifying the Risks of Disturbances to the Functions and Values of Wetlands

Not all human-caused disturbances will result in significant impacts to the functions and values of wetlands in a jurisdiction. Once all the possible disturbances have been identified (as discussed in the previous section), the next step in the characterization of risks is to identify which of the proposed land-use actions have the greatest risk of impacting wetlands (see third column in Table 10-1). This task is best done using maps, especially at the scale of the management area. The process described in Chapter 5 for performing a landscape analysis can be used to identify what parts of the landscape within the management area are sensitive to the different types of disturbance and risks that may be generated by proposed land use actions.

For example, if wetlands are located in an area zoned as urban or residential and the area serves to recharge an aquifer, then the risk to these wetlands is high as a result of the impervious surfaces created. Creating impervious surface in areas where water infiltrates rapidly into groundwater creates a risk to wetlands that rely on that groundwater.

Regulations that focus on the wetland sites themselves (site scale) can also be analyzed in terms of the risks they pose to wetlands. Using the example used previously, the exemption of single-family residences in the buffer of a wetland would pose a much

higher risk to wetlands that have a high habitat value than those that function poorly as habitat.

Corrective actions (regulatory and non-regulatory) should also be considered when assessing risks. Areas that are proposed for restoration or preservation, for example, should be considered in terms of how these actions might reduce the risks to wetlands. For example, the restoration (by non-regulatory means) of a diked field to a floodplain wetland identified in the landscape analysis as important for restoring hydrologic processes, reduce the overall risk to the jurisdiction from losses of hydrologic functions in other locations targeted for development.

10.3.3 Proposing Measures to Minimize the Risk or Replace the Resource at Risk

If the characterization of risks indicates that some of the policies, regulations, or plans pose a risk to the functions and values of wetlands in a jurisdiction, it is important to identify what actions can be taken to minimize this risk. Using a previous example, if a comprehensive plan calls for urban development in an area where groundwater is recharged, the risk to the aquatic resources can be reduced by requiring that all runoff be infiltrated on site or that paved areas use some of the more innovative approaches such as permeable surfaces.

A summary table such as that shown in Table 10-2 can be used to document the risks identified and the actions taken to minimize risks.

Table 10-2. An example of a table summarizing the risks of land-use actions and measures to minimize the risks.

Action	Disturbance Caused by Action	Risk of Disturbance to Wetland Functions and Values	Measures to Minimize Risk	Does This Reduce Risk to an Acceptable Level?
Urban zoning in a recharge area outside of wetland	Change in water regime, increased surface runoff, and less infiltration	High for wetlands fed by groundwater and for those that will receive the direct runoff from paved surfaces	Change development standards in recharge area to require all surface water to be infiltrated	Yes
Permit fill of wetlands	Change in structure of wetland and loss of wetland area	High for functions within wetland	1. Require compensation at ratios that will ensure no net loss 2. Ensure compliance 3. Do not permit fill in wetlands that cannot be replaced (e.g., bogs)	Maybe

The King County example of a characterization of risk

As part of revisions to its critical areas ordinance, King County has prepared an *Assessment of Proposed Ordinances* that describes the risks to resources from the county's proposed regulatory and non-regulatory actions. Section 2.9 from Chapter 2 of the King County report describes the risks to the wetland resource from actions such as specified buffers, allowed alterations, classification (rating), and mitigation requirements. This section of the King County report is reproduced in Appendix 10-A of this volume. The full report is available on the web at http://www.metrokc.gov/ddes/cao/.

By first identifying and categorizing the risks to wetland resources and then identifying the actions necessary to minimize those risks a local jurisdiction will be in a better position to make decisions that incorporate existing scientific information. The characterization of risk can also be used as the first step in a program of adaptive management (see Chapter 12). Actions deemed to be of different levels of risk can be monitored to determine if the initial conclusions were valid.

Chapter 11

Taking Actions: Regulatory and Non-Regulatory Activities

11.1 Introduction

This chapter discusses Step 3 of the four-step framework, taking actions to reduce risks to the wetland resource (Figure 11-1). In Step 3, the regulatory and non-regulatory solutions, developed for a wetland protection program during Step 2, are implemented. The solutions are described in Chapters 6, 7, 8 and 9, whereas characterizing the risks of implementing those solutions is discussed in Chapter 10.

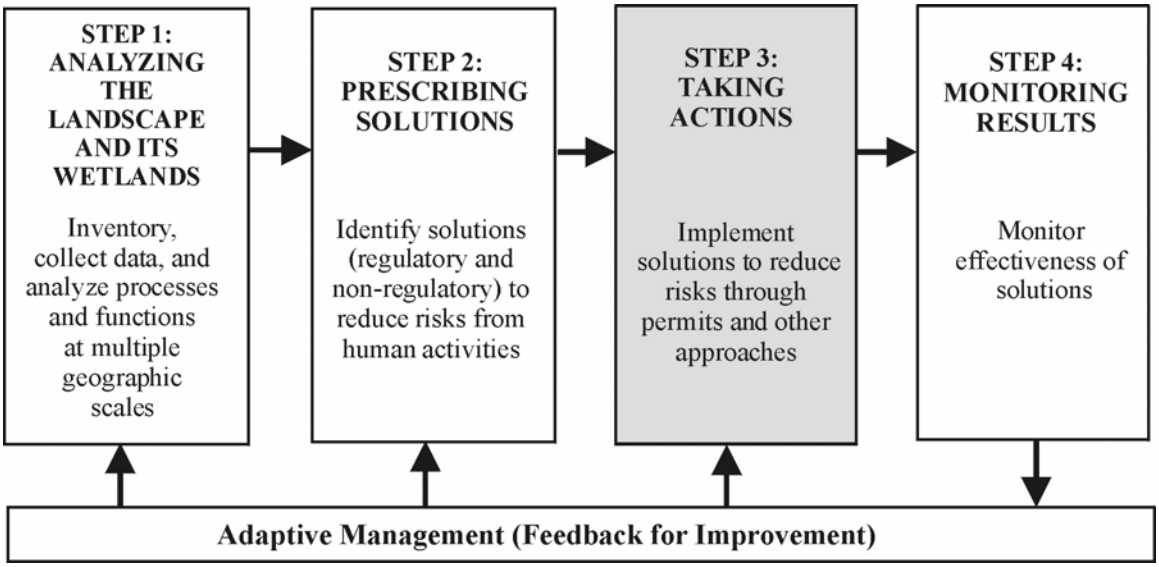

Figure 11-1. Implementing regulatory and non-regulatory components of a wetland protection program is Step 3 in the four-step framework presented in this volume (shaded box).

The chapter is divided into two major sections: implementing the regulatory and the non-regulatory components of a wetland protection program. As mentioned previously, both are needed to effectively protect and manage wetlands.

11.2 Implementing the Regulatory Component of a Protection Program

The single most important element in ensuring effective implementation of the regulatory component is having adequately trained staff or a qualified professional on contract. Other important elements include:

- A process to review permits that is clear and uses a team approach
- Inspecting the wetland site during construction of the development project
- Monitoring the wetland during and following construction
- Enforcing regulations
- Monitoring the effectiveness of regulations

The elements listed above require adequate funding for effective implementation. Local governments should include provisions, such as fees for permit review, for adequate funding of all the elements. It is also important to have an educational element such as materials for permit applicants and interested citizens.

11.2.1 Adequately Trained Staff or Qualified Wetland Professional

Local governments benefit greatly from having trained staff or access to qualified wetland professionals to implement their regulations, to make decisions where discretion is required, and to work with and review the materials submitted by the applicant's consultants. Most regulations pertaining to wetlands allow for some discretion in application to site-specific situations. They may pertain to site-specific buffer adjustments, stormwater considerations, or mitigation ratios. Even when regulations are written in a prescriptive fashion, many applicants and/or their consultants may make a case for why their projects should be granted some flexibility based on site-specific considerations over and above that allowed by the regulations.

In many instances, an applicant's consultant may be an individual with extensive experience and credentials in wetland science and it can be difficult for a local regulator to respond in a reasonable and appropriate manner to such requests. Additionally, while most applicants and their consultants provide accurate and complete information, occasionally a regulator will be confronted with information that is inaccurate or incomplete. It is critical that the local staff responsible for implementing wetland regulations have the knowledge or resources to effectively review submitted information and determine if it is accurate and complete.

Therefore, to effectively implement regulations, local government staff or wetland professionals on contract should have at least a basic familiarity with the following topics:

- Wetland identification and delineation
- Wetland rating
- Wetland function assessment
- Direct and indirect impacts to wetlands from different types of development projects
- Compensatory wetland mitigation, including site selection and design, construction oversight, monitoring, and maintenance
- Land-use regulations
- Writing permits and applying necessary conditions

The following resources can be used when becoming familiar with the basics of wetland regulation: Ecology's publications on wetland programs (www.ecy.wa.gov/programs/sea/ wetlan.html); periodic training offered by Ecology and other resource agencies; training classes provided by private vendors; and coursework such as the University of Washington's Certificate Program in Wetland Science and Management (www.extension.washington.edu/ext/certificates/wet/wet_gen.asp). Portland State University also offers various courses in wetland science and management through its Environmental Professional Development Program (www.esr.pdx.edu/epp/).

Some larger jurisdictions have one or more wetland professionals on staff. Most jurisdictions, however, rely on planning and general regulatory staff that have many responsibilities and who may not have the expertise in wetland ecology and management in order to effectively administer wetland regulations. To address this situation, many jurisdictions contract with a third-party wetland professional to provide the knowledge and experience needed to review proposals for changes in land uses such as development proposals. Considerations for choosing a qualified third-party wetland professional are discussed in Appendix 8-H, Hiring a Qualified Wetlands Professional.

11.2.2 The Process for Reviewing Permits

The process for review of permit applications for land development should be clear to both the applicant and the regulator. A local jurisdiction can require a separate permit for work in or near wetlands, or they can incorporate review for conformance with their wetland regulations into other permit review processes (see Appendix 8-B, the section on applicability). Regardless, the process for reviewing permit applications should include close coordination among appropriate regulatory staff, especially between those responsible for wetland protection, stormwater management, clearing and grading, and construction inspection.

Review of permit applications involving wetlands should at a minimum include a site investigation to verify delineation of the wetland boundary and confirmation of the rating of the wetland. Review for more complex projects that will alter wetlands should include assessment of wetland functions, analysis of project impacts, and review of proposed mitigation to compensate for adverse impacts. Some projects may require additional hydrologic analysis to ensure that wetland hydrology is not adversely affected. In such situations a hydrologist with understanding of wetland functions should become part of the review team to ensure that the project's stormwater management plan takes the wetland's hydrology into account.

Review of permit applications involving wetlands should result in written recommendations for approval, denial, or conditioning of the permit. Regulatory staff and/or qualified, third-party wetland professionals may be required to testify before the local Hearings Examiner to support decisions made during the review of the permit for certain types of applications.

11.2.3 Inspecting and Monitoring the Wetland During Construction

It is important that the conditions or wetland protection measures applied to permits upon their approval are in place and on the ground during and after construction of the project. For example, inspections during construction should ensure that clearing of vegetation is outside the wetland buffer or otherwise consistent with the approved plans and that measures for erosion and sediment control are protecting the wetland's water quality. Erosion and sediment controls should be in place and clearing limits well marked and easily visible on the ground.

When compensatory wetland mitigation is required for a permit, it is essential that the local jurisdiction inspect the mitigation project to see that it has been installed in accordance with the approved plans. Inspections at mitigation sites should take place annually or as specified on the approved mitigation plan to ensure that the project will be successful in compensating for the lost wetland functions.

11.2.4 Enforcing Regulations

Unfortunately, at times wetlands are altered without approval through a permit. A local jurisdiction should have specific authority in their critical areas ordinance to investigate the affected wetland, issue "stop work" orders (see Appendix 8-B), and require remediation of any violation. This includes the ability to require restoration of affected wetlands and/or compensatory mitigation for the reduction or loss of wetland functions. Effective enforcement often requires penalties for the unauthorized alteration of wetlands. These enforcement activities require adequate staff to investigate the initial violation, follow up on remediation, and coordinate with state and federal agencies as appropriate.

11.2.5 Monitoring the Effectiveness of Regulations

Local jurisdictions should create a tracking system to monitor the effectiveness of regulations in protecting wetlands. At a minimum, the jurisdiction should account for the acreage of wetlands altered as a result of permit activity and the success of compensatory mitigation projects. Evaluation of the results of the tracking system can be used by a local jurisdiction to revise regulations or procedures to provide better protection for wetlands. Please refer to Chapter 8 (Section 8.4) and Chapter 12 for additional discussion on monitoring the effectiveness of a wetland protection program. The tracking system can also be used to keep track of unauthorized activities in the jurisdiction.

11.2.6 Educational Materials

Many landowners and project applicants find it difficult to understand regulations and the requirements for permit application. Additionally, some landowners do not understand why wetlands are important and why regulations are needed. Brochures and other informational materials that discuss these topics and explain how applicants can get assistance can be very helpful and save regulatory staff a lot of time. Providing a clear explanation of the process for reviewing permits, such as a flow chart, can also be important to applicants. While general materials on some of these topics are available from federal and state agencies, materials developed locally are very useful.

11.3 Implementing the Non-Regulatory Component of a Protection Program

As with the regulatory component of a wetland protection program, implementing non-regulatory actions specified in plans and polices such as Green Infrastructure plans, Alternative Futures analysis, or comprehensive plans (discussed in Chapters 6, 7, and 9) requires dedicated staff to coordinate and support conservation, preservation, and restoration activities and manage sites. Other important elements include:

- Identifying, mapping, and prioritizing where non-regulatory tools should be applied
- Creating partnerships with organizations, government agencies, and others to help sponsor local projects
- Identifying a recipient to hold and manage land
- Obtaining funding for local actions
- Providing incentives to encourage participation by landowners

- Educating and involving the public and providing technical outreach to landowners
- Monitoring project sites
- Monitoring the overall success of the non-regulatory actions

An overview of each of these elements is provided below.

For more information about setting up a non-regulatory component of a wetland protection program, see *Designing Wetland Preservation Programs for Local Governments: A Guide to Non-Regulatory Protection* (Rubey 1992). This document is somewhat dated but still offers a general discussion of some of the topic.

11.3.1 Staffing the Non-Regulatory Component

It is optimal to have a dedicated coordinator overseeing the non-regulatory component of a wetland protection program. A coordinator would facilitate the numerous actions (e.g., restoration or preservation of high-priority areas that can be sponsored through the local government or through partnerships with other organizations. A coordinator would also work with private landowners to conserve the land through mechanisms such as conservation easements (see Chapter 9 for a description of non-regulatory tools). The following is a list of tasks a coordinator might oversee:

- Identifying appropriate sites for preservation and restoration
- Working with landowners to apply better conservation practices
- Establishing and updating incentive and funding mechanisms
- Engaging in education and outreach activities
- Providing technical assistance for non-regulatory actions
- Facilitating local projects sponsored by the local jurisdiction (obtaining grants, forming partnerships, developing the technical design, conducting site monitoring, etc.)
- Supervising support staff or volunteers working on non-regulatory actions
- Coordinating with other departments within the jurisdiction and with other organizations and agencies

The coordinator may perform all or some of these tasks depending on the number of staff available as support. The number of staff dedicated to implement the non-regulatory component of a protection program usually reflects the size of the local government and its emphasis on incorporating a non-regulatory approach.

11.3.2 Identifying, Mapping, and Prioritizing Sites

Identifying, mapping, and prioritizing sites for non-regulatory activities are best started during early planning stages such as landscape analysis, Green Infrastructure planning, or Alternative Futures analysis (see Chapters 5 and 6 for further discussion). If these plans have not been completed by the local jurisdiction, then non-regulatory actions such as acquisition and restoration could occur as opportunities arise. In addition, a jurisdiction could decide on potential projects based on technical reports and studies that point to desirable sites. In either case, projects will usually need to be prioritized and implemented sequentially.

Additional review and strategizing will probably be needed as implementation of the non-regulatory program begins. This might involve sorting through the various sub-basins or sensitive landscape areas within the entire management area to focus on sites with immediate threats or opportunities and deciding what projects can be funded over the immediate fiscal period. Prioritizing will likely be conducted on an ongoing basis as funding, staff, and opportunities fluctuate.

11.3.3 Creating Partnerships for Locally Sponsored Projects

Local governments benefit from partnerships with other agencies or organizations to successfully implement non-regulatory projects. Completing transactions associated with conservation, preservation, and restoration (e.g., purchasing, restoring, monitoring, managing sites, etc.) can be complex and take time. The following organizations are available to work with local governments on non-regulatory actions.

Land trusts offer the services of brokering land acquisitions, raising funds to purchase sites, and educating landowners about tax benefits and incentives. Land trusts protect land permanently. They work directly with landowners during transactions to acquire land. Land trusts are knowledgeable about the resources and the advantages of land preservation in regard to property taxes. They are perceived as non-adversarial by landowners (see Appendix 9-A). In addition, land trusts often attract the voluntary assistance of retired professionals who can provide technical assistance with site assessments and monitoring.

For example, a national land trust called the Trust for Public Land (TPL) will assist in securing properties for governments when funding is pending and the time available to preserve a parcel is short. TPL releases the property to the jurisdiction later when funding is available.

Partnerships with other **non-profit organizations** such as the local Audubon Society or Ducks Unlimited may be essential to completing site monitoring tasks (such as bird counts on restored wetlands) and for implementing actual site restoration plans.

State and federal agencies are also excellent partners to assist with non-regulatory efforts. These agencies can help with securing grant funds for projects. They can also

offer technical knowledge about wetland functions, restoration techniques, and long-term management. Agency assistance is provided at no charge to the local jurisdiction.

Either **internal coordination** or **internal partnerships** will also be needed between various department and staff within the local government (such as parks or public works departments). As discussed below, they may be the recipients of lands that have been purchased and/or restored.

Information on land trusts and other partners, as well as funding program opportunities, can be found in the publication *Exploring Wetlands Stewardship: A Reference Guide for Assisting Washington Landowners and Communities* (Rubey 2004).

11.3.4 Identifying a Recipient to Hold and Manage Land or Rights to Land

A local department such as parks or public works should be identified to receive and manage properties that are purchased or donated. For example, direct preservation of key critical areas is essential to maintaining landscape processes through time. Therefore, preservation resulting in permanent protection of land through *full-fee title* (ownership of all property rights) may be the best mechanism to use (see Chapter 9 for a description of full-fee). In such cases, as with restoration efforts, a recipient is needed for managing and monitoring the site.

Who the recipient should be will depend on whether or not the local jurisdiction buys land in full-fee and wishes to own and manage the land over time. If not, site ownership and management (or holding a conservation easement) may be handled by an external partner such as a land trust. However, a land trust usually requires an endowment to manage a site. Alternatively, property could be passed to a state agency. However, state agencies may not be willing to accept management of new properties. Therefore, as mentioned above, it is important to identify willing organizations and create partnerships for receiving and managing land as well as coordinating other aspects of conservation, restoration, and preservation projects.

11.3.5 Establishing Funding Mechanisms and Incentives for Landowners

Funding mechanisms and landowner incentives were reviewed in Chapter 9. These tools play an essential role in the non-regulatory component of a protection program. Obtaining funding is an absolute necessity to a local government that wishes to conduct voluntary preservation and restoration projects. Without a local funding source to provide a match, a local government cannot apply for state and federal grant programs. As mentioned elsewhere in this volume, lists of funding programs are provided in *Exploring Wetlands Stewardship: A Reference Guide for Assisting Washington Landowners and Communities* (Rubey 2004).

One very strong funding tool that can be established by a local government is the Conservation Futures Levy. This levy can be implemented by legislative ordinance and a portion of the funds dedicated to preservation and restoration projects (see Chapter 9 for further details). It may also be appropriate for a local government to use the funds generated to finance "engineered infrastructure," such as levies for *special purpose districts* and *in-lieu fees* as well as general funds, to implement non-regulatory actions (i.e., preservation and restoration) to maintain the services provided by "green infrastructure."

Landowner incentives are also essential for engaging citizens in voluntary conservation actions and are discussed in detail in Chapter 9. In particular, local jurisdictions may wish to consider the value of establishing a watershed-based Public Benefit Rating System (PBRS) to implement their Current Use Taxation Program for "Natural" Open Space. As discussed in Chapter 9, the results of a landscape analysis can be integrated into a PBRS program.

11.3.6 Educating and Involving the Public

Education and public involvement are vital parts of a non-regulatory effort, both initially and on an ongoing basis. The importance of education and public involvement is demonstrated by its inclusion and emphasis in Green Infrastructure planning, Alternative Futures analysis, and the development of comprehensive plans (as discussed in Chapters 6 and 7).

Education is essential because it provides the public with an accurate understanding of why non-regulatory efforts are valuable to the community, as well as to maintaining and restoring landscape processes. For example, decision-makers and the public should be informed that the expenditures needed for conservation, restoration, and preservation are justified when compared to long-term costs. When landscape processes are maintained or improved, the public saves; engineered infrastructure that would be built to replace lost services (functions) is not needed (see Chapter 6 for information on the fiscal savings of non-regulatory efforts).

Education and outreach efforts are also key factors in increasing enrollment in incentive programs that foster conservation of the land. Likewise, they encourage the public to get involved through voluntary actions either on their own property or by supporting local projects (e.g., volunteers monitoring sites). In so doing, education and public involvement can also improve support for regulatory protection.

11.3.7 Monitoring Preservation and Restoration

When preserving and/or restoring wetlands, it is important that the local jurisdiction implement monitoring at both the site level and the program level.

At the site level, it is recommended that local governments:

- Allocate Conservation Futures dollars, or other funds, to secure properties and fund restoration activities
- Engage in restoration actions such as breaching dikes, removing exotic plants, planting native vegetation, etc.
- Monitor site conditions and manage preserved and restored lands

At the program level, it is recommended that local governments monitor the effectiveness of the success of the following elements to provide feedback for adaptive management:

- Goals for preservation and restoration that are aligned with the objectives of plans such as Green Infrastructure or conservation plans
- Incentive programs for landowners, such as current use taxation
- Education programs for citizens about local stewardship activities
- Technical assistance for landowners

Monitoring and adaptive management is discussed in more detail in Chapter 12.

Chapter 12
Monitoring and Adaptive Management

12.1 Introduction

This chapter discusses two aspects of the framework of a program for protecting wetlands: 1) *monitoring results*, determining the effectiveness of the program (Step 4) and 2) *adaptive management*, a feedback mechanism for making improvements to the program if needed (Figure 12-1). Monitoring and adaptive management have often been low on the list of priorities for local jurisdictions. Funding, the availability of staff, and technical issues make establishing a monitoring program difficult for some jurisdictions. In addition, monitoring may also expose what are perceived as failures and may require changes that are difficult or unpopular (Washington State Joint Natural Resources Cabinet 1999).

However, the benefits of a successful monitoring program and the changes that may result from it can be substantial. Many actions taken to protect and manage wetlands have to be considered as experiments because we have not tracked their success in the past.

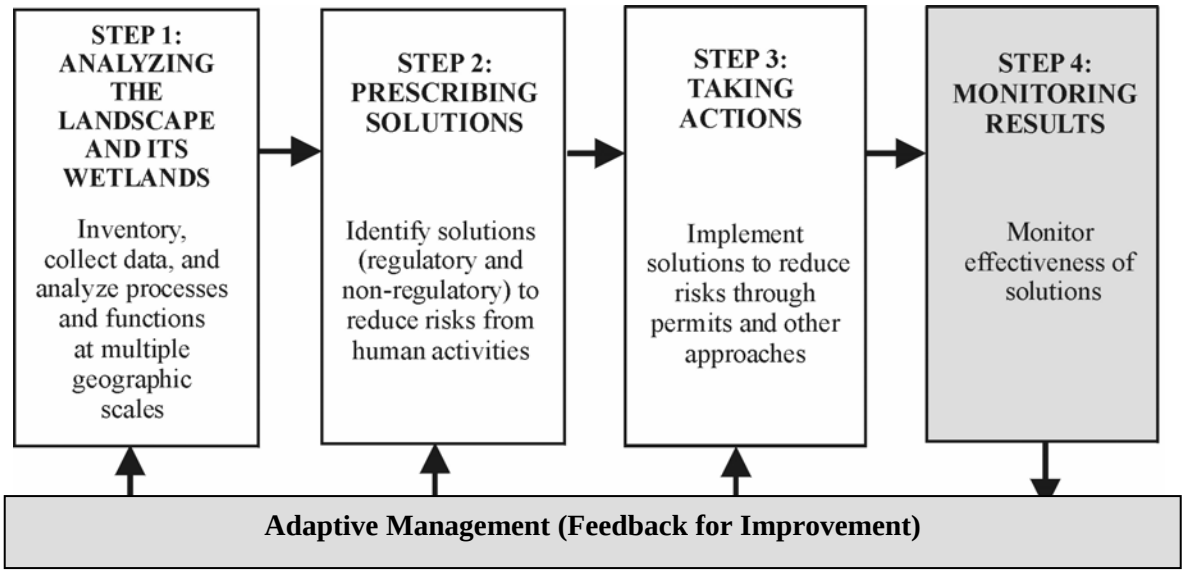

Figure 12-1. Monitoring is Step 4 of the four-step framework discussed in this volume, and Adaptive Management provides feedback for improving wetland protection programs (shaded box).

We do not know, or fully understand, all the cause and effect relationships between human actions on the land and the functions performed by wetlands (see Chapters 3 and 4 in Volume 1). Thus, we cannot fully predict the outcome of actions taken to protect and manage wetlands, other natural resources and critical areas, as well as landscape processes. Monitoring the effectiveness of protection measures in the context of adaptive management is the most efficient way to face this uncertainty. Adaptive management is a commitment by a local government to change approaches for protecting and managing wetlands and to redirect resources as warranted by new information. A willingness to make improvements to address insufficiencies identified through this monitoring step is important.

The focus is to monitor the effectiveness of solutions identified and actions taken in Steps 2 and 3 (described in previous chapters) and make changes as needed. The process is iterative as shown in Figure 12-2. The goal is to implement a system for modifying past decisions, if needed, that is based on information generated from monitoring the specific actions taken and on any scientific information that is newly available. Plans, regulations, and other actions should be reconsidered if the monitoring data show there are further losses of wetland functions and values. This will help to reduce cumulative impacts to wetlands and other resources.

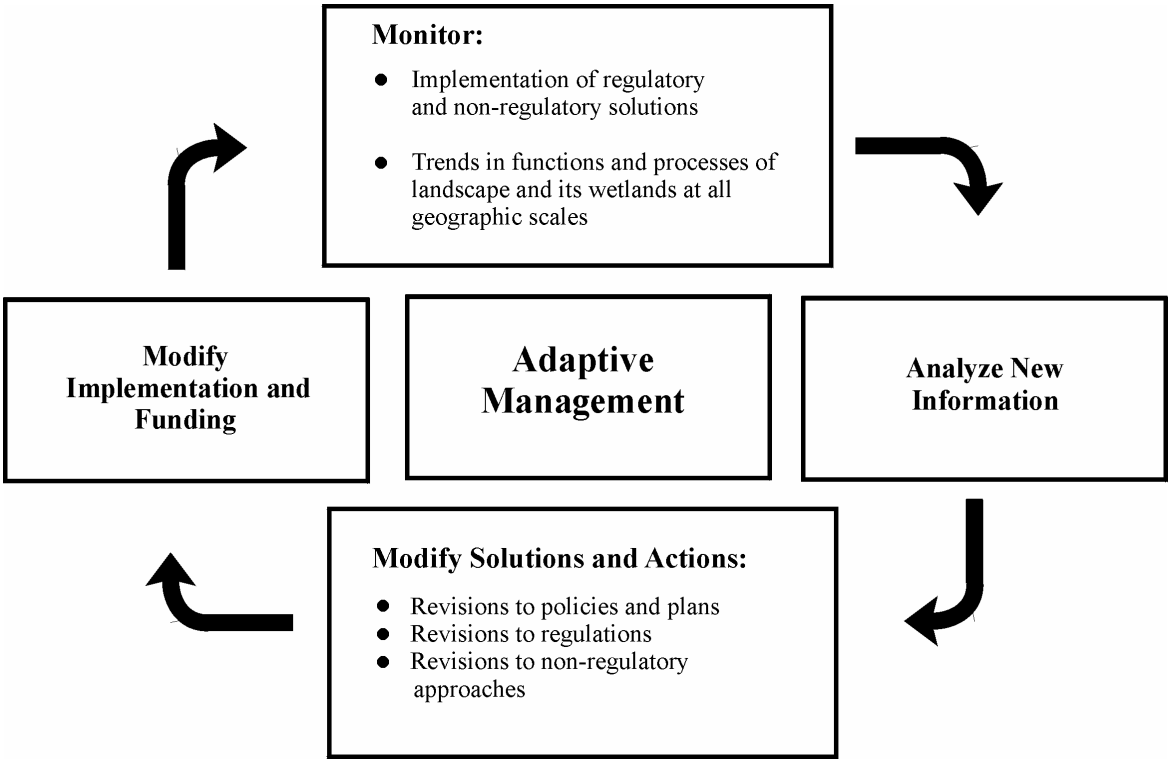

Figure 12-2. Conceptual representation of how wetlands can be protected and managed using adaptive management. Adaptive management implies that the process does not end with the completion of the four steps but keeps cycling.

12.2 What Should Be Monitored?

Monitoring associated with protecting and managing wetlands by local jurisdictions can be divided into three categories, as listed below. All aspects of monitoring are important in providing feedback to guide decisions for adaptive management. If the functions and values of wetlands are not adequately protected, managers need to know whether this results from inadequate implementation, inadequate standards, or inadequate strategies.

- **Monitoring trends** tracks landscape processes and wetlands over time at all geographic scales and records changes in functions and values at individual wetlands. The monitoring should determine if the goals and objectives established for the wetland resource by a local jurisdiction are being met. Monitoring trends is critical in interpreting the effectiveness of efforts to protect and manage wetlands. By monitoring trends, it is possible to document if cumulative impacts continue to occur.

- **Monitoring implementation** addresses the extent to which plans have been implemented and the extent to which regulatory and non-regulatory actions proposed in those plans and regulations have been taken. This type of monitoring provides a basis for tracking the actions taken and for quality assurance.

- **Monitoring the effectiveness of strategies** addresses how effectively the complete program, not just individual plans and actions, meets explicit objectives or conditions desired for the future.

Different approaches are needed to monitor at different geographic scales because the type of data collected is different. In addition, the objectives of a monitoring program may be met in many different ways, not all of which require extensive collection of data. It is not the intent of this chapter to describe the different monitoring approaches and methods that can be used. These will depend on the wetland resources present in a local jurisdiction, the goals and objectives set by that jurisdiction, the solutions they propose, and the actions they take.

The following sections outline some of the basic questions that need to be addressed when monitoring for an adaptive program for wetlands.

12.2.1 Monitoring Trends in the Resource

The goal of monitoring trends in wetlands is to understand if, and how, the landscape and site-specific processes that control structure and functions within a wetland(s) have been altered as a result of changes in land use. The resource needs to be monitored at all geographic scales used in the analysis of the resource (i.e., the contributing landscape, the management area, and the site scale).

The analysis can be undertaken using the guidance discussed in Chapter 5. Regardless of the methods used, however, there is one major question that needs to be addressed through monitoring: *Have changes in land use altered landscape processes to the extent that they impact the functions of wetlands in a jurisdiction?* Changes to processes and functions can be either negative (indicating further degradation), no change (indicating efforts at protecting existing levels of processes and functions are working), or positive (indicating that efforts at restoration are succeeding).

Monitoring trends at the landscape scale involves identifying:

- If the major sources of water to wetland(s) and flow paths have changed (either degraded or restored)
- If the major sources of sediment have changed
- If the major sources of nutrients have changed
- If the major sources of toxic compounds have changed
- If there has been an increase in the fragmentation of wildlife habitats

Monitoring trends at the wetlands themselves involves tracking how the functions and values of each individual wetland within a jurisdiction have changed. Continuously monitoring all wetlands, or even a random subset of them, in a jurisdiction is optimal but may not be feasible because of the cost. In the absence of such a program, it is suggested that a local jurisdiction track trends by analyzing the wetland assessments that applicants submit when they propose actions at individual sites. Qualitative trends can be tracked by noting the overall changes in the functions of wetlands being proposed for alteration within each hydrogeomorphic class (depressional, riverine, etc.) or wetlands of particular concern such as bogs and mature, forested wetlands.

The restoration of wetland functions at sites used for restoration should also be monitored to determine if the objectives of the projects are being met.

12.2.2 Monitoring the Implementation of Protection Measures

Monitoring implementation addresses the extent to which the solutions or actions proposed for protecting and managing wetlands, as developed in Step 2 (Prescribing Solutions), have actually been put into practice or carried out.

12.2.2.1 Monitoring Implementation at the Scale of the Contributing Landscape

Whether monitoring the implementation of solutions needs to take place at the scale of the contributing landscape depends on whether the contributing landscape falls entirely within the jurisdiction or if it includes several jurisdictions. In the former case, monitoring the contributing landscape is actually the same as monitoring the management area, described below. If the contributing landscape spans several jurisdictions, then monitoring at this scale is needed and should be based on the objectives of the plans and solutions developed among the jurisdictions.

It is not possible in this document to cover how to monitor all the possible watershed plans, regional plans, actions taken as a result of various partnerships, etc. However, it is important that each objective identified in such plans should have associated with it measures for monitoring its implementation. For example, a watershed plan may have an objective that all jurisdictions in the watershed adopt the same method for rating wetlands to ensure that wetland functions are characterized in the same way throughout the watershed. Monitoring this objective would involve examining the adoption and implementation of the chosen wetland rating system.

12.2.2.2 Monitoring Implementation at the Scale of the Management Area

Monitoring the implementation of solutions developed for the management area is a matter of keeping accurate records of the actions taken by the jurisdiction to protect and manage wetlands, and a commitment to compile and analyze the data at specified intervals. The analysis should include the actions actually taken compared to the solutions and actions proposed in the original comprehensive plan, critical areas ordinances, shoreline master programs, etc. For example, a critical areas ordinance may state that each permit that will result in a wetland impact requires that the wetland be rated on its functions and values. Monitoring the implementation of this would require an examination of how many permits were issued with a completed rating as well as how many were issued without a rating.

This type of monitoring should also be applied to non-regulatory programs. For example, if a jurisdiction has a program to acquire conservation easements on lands that it considers important to maintaining landscape processes, it should monitor how many easements have been acquired compared to the total number needed. Table 12-1 lists some of the common solutions used by jurisdictions in protecting and managing wetlands.

Table 12-1. Monitoring common solutions to protecting and managing wetlands at the scale of the management area. These are only a few examples, not an inclusive list of all that a jurisdiction should monitor.

Action	What to Monitor
Zoning	Number of zoning variances permitted
Development standards for areas sensitive to disturbance	Number of variances permitted
Setbacks, such as buffers or "no-spray" zones, to protect resources	Number of variances to setbacks permitted Number of violations
Preservation of important wetlands	Number of acres with conservation easements or fee title
Conservation of wetland resources	Number of acres enrolled in Current Use Taxation program or other applicable programs
Voluntary restoration of wetlands	Number of acres and types of functions successfully restored

12.2.2.3 Monitoring Implementation at the Site Scale

Monitoring the implementation at the site scale is a matter of keeping accurate records of the permits approved and other actions taken at individual sites. This includes, for example, monitoring the success of follow-up site visits, compliance with permit conditions, restoration efforts, and enforcement actions. The review of the scientific information presented in Volume 1, Chapter 6, highlighted the fact that many projects that compensate for impacts to wetlands are not successful because there has been no follow-up. Therefore, follow-up on projects is very important. As previously mentioned, this data can be used to ascertain general trends regarding the effectiveness of wetland protection and management in the jurisdiction.

12.3 Adaptive Management

Adaptive management has been defined in various ways since its development in the early 1970s. Different people and organizations continue to have somewhat differing views of the best definition for their purposes. In order to bring some consistency and clarity, the following working definition for this concept is used here:

> *Adaptive management is a systematic process for continually improving management policies and practices by learning from the outcomes of previous policies and practices.*

As mentioned earlier in the chapter, the goal of adaptive management, in the context of protecting and managing wetlands, is to implement a repetitive process for making decisions that is guided by scientific information that is newly available and data collected and analyzed through the monitoring program. The iterative nature of the process is shown in Figure 12-2. The results of the monitoring program provide the basis for revising past decisions, and these improved actions and solutions are subsequently monitored to determine their success in meeting the jurisdictions goals for protecting resources.

Adaptive management is based on the assumption that managed ecosystems are complex and inherently unpredictable. The approach incorporates the fact that, at present, humans do not know enough to adequately manage environmental resources. Adaptive management, from this perspective, treats management policies and practices as experiments, and it serves to assess the responses of natural resources as human behavior changes (Lee 1999). The goal is to learn and change objectives as needed. However, this has often not been considered the mark of a good manager, who is rewarded instead for steadfast pursuit of objectives (Lee 1999). The important point to stress is that adaptive management will only work if there is a willingness to actually change polices and practices as a result of monitoring.

Some of the characteristics of adaptive management are:

- Acknowledgement that there is still much uncertainty about what policy or practice is best for solving each particular issue related to protecting and managing wetlands
- Careful design and implementation of a monitoring plan designed to reveal the knowledge that is currently lacking
- Monitoring of both the resource itself and the implementation of plans and practices used to protect the resource
- Analysis of the outcomes of policies and practices in terms of the original objectives
- Incorporation of the results into future decisions

A brief history and additional resources for adaptive management

The text below is adapted from the University of Oregon (http://oregonstate.edu/instruction/anth481/ectop/ecadm.html).

C.S. Holling and several colleagues developed the concept of adaptive management at the University of British Columbia's Institute of Resource Ecology in the late 1960s. Adaptive management reached the scientific literature in Holling's book, *Resilience and Stability of Ecological Systems*, published in 1978. The emphasis of the Holling approach is to experiment to learn the boundaries of natural systems. Holling and his colleagues worked with resource managers in British Columbia on a number of management experiments and workshops designed for public participation, thereby testing the process.

Adaptive management became an important concept in resource management in the United States when K.N. Lee introduced it to the Northwest Power Planning Council in 1984. Lee studied adaptive management with Randall Peterman, who in February 1984 gave a talk about experimental management. Subsequently, different forms of adaptive management have become part of the Northwest Forest Plan, the Oregon Plan for Salmon and Watersheds, the Oregon Department of Forestry Plan to manage state forests, and many other processes for resource planning.
